ABSTRACT

Two ocean general circulation models are used to test the ability of geostrophic velocity measurement systems to observe the Meridional Overturning Circulation (MOC) and meridional heat transport (MHT) in the South Atlantic. Model sampling experiments are conducted at five latitudes (between 15°S and 34.5°S) spanning the range of extratropical current regimes in the South Atlantic. Two methods of estimating geopotential height anomalies and geostrophic velocities are tested, simulating dynamic height moorings (T, S array) and current and pressure recording inverted echo sounders (CPIES array) deployed within the models. The T, S array accurately reproduces the MOC variability with a slight preference for higher latitudes, while the CPIES array has skill only at higher latitudes due to the increased geopotential height anomaly signal. Whether direct model velocities or geostrophic velocities are used, MHT and the MOC are strongly correlated, and successful reconstruction of MHT only occurs when there is skill in the MOC reconstructions. The geopotential height anomaly signal is concentrated near the boundaries along 34.5°S suggesting that this is an advantageous latitude for deployment of an *in situ* array. Four reduced arrays that build upon the sites from two existing pilot arrays along 34.5°S were examined. For these realistically-sized arrays, the MOC and MHT reconstructions from the T, S and CPIES arrays have comparable skill, and an array of approximately 20 instruments can be effectively used to reproduce the temporal evolution and vertical structure of the MOC and MHT.

1. Introduction

The Atlantic component of the meridional overturning circulation (MOC) includes the sinking of surface waters at higher latitudes in the North Atlantic, meridional translation of these deep waters and other remotely formed water masses around the world, gradual upwelling, and a return to the deep water formation regions through the South Atlantic. This overturning circulation is composed of wind-driven transports and the buoyancy-forced thermohaline circulation (Lee and Marotzke 1998). To compute the strength of the MOC in an ocean basin along a line of constant latitude, one needs to measure the total meridional flow across the line. Practically, to do this geostrophic velocity measurement techniques are employed (e.g, geostrophic currents are computed from zonal sections of density profiles and bottom velocity measurements), and are combined with zonal wind stress measurements across the basin. Unfortunately, cross-basin measurements suitable to estimate geostrophic transport have historically been limited to a few hydrographic sections (e.g., Ganachaud and Wunsch 2000; Ganachaud 2003; Lumpkin and Speer 2007) that at best provide snapshots of the MOC, from which it is challenging and controversial to assess long-term variations and trends (e.g., Bryden et al. 2005; Cunningham et al. 2007; Kanzow et al. 2010).

At present the only existing time series of basin-wide MOC transport is in the subtropical North Atlantic. With the inception of the Rapid Climate Change/Meridional Overturning Circulation and Heat Flux Array (RAPID/MOCHA) array along 26.5°N in April 2004, continuous-in-time estimates of the MOC and meridional heat transport (hereafter MHT) are now available. The RAPID/MOCHA array, coupled with the long-term NOAA Western Boundary Time Series (WBTS) program in the Florida Straits and east of the Bahamas,

49 merges *in situ* data from dynamic height moorings (tall moorings with temperature, salinity
50 and pressure recorders) augmented with current meters, pressure equipped inverted echo
51 sounders (PIES), PIES augmented with current meters 50 m above the seafloor (CPIES),
52 and a submarine telephone cable, with satellite-based wind measurements (e.g., Baringer
53 and Larsen 2001; Meinen et al. 2006; Cunningham et al. 2007). Model-based sampling
54 experiments using geostrophic velocity measurement techniques were first conducted prior
55 to the deployment of this basin-wide MOC observing system (Hirschi et al. 2003).

56 The limited collection of hydrographic sections in the South Atlantic has hampered efforts
57 to understand the impact of the South Atlantic on the global MOC. Models and observations
58 suggest that the South Atlantic is not a passive conduit for remotely formed water masses as-
59 sociated with the MOC, such as Antarctic Bottom Water and Circumpolar Deep Water (e.g.,
60 Hogg et al. 1999; Zenk et al. 1999), and that it actively participates in water mass trans-
61 formations, particularly in regions of high meoscale variability such as the Brazil/Malvinas
62 Confluence and at the Agulhas Retroflexion (Schouten and Matano 2006, Jullion et al.
63 2010; Garzoli and Matano 2011 and references therein). Models and observations also show
64 that the South Atlantic plays a significant role in the establishment of oceanic teleconnec-
65 tions (e.g., Speich et al. 2007). This highlights the need for sustained observations in the
66 South Atlantic, which, in conjunction with modeling efforts, would improve understanding
67 of the processes necessary to formulate long-term climate predictions. The U.S. Climate
68 Variability and Predictability Research Program (CLIVAR) Atlantic MOC (AMOC) imple-
69 mentation strategy calls for a MOC and MHT monitoring array across the South Atlantic
70 (<http://www.usclivar.org/plans.php>), and three South Atlantic MOC (SAMOC) workshops
71 have been held to design the basis for an observational program (Garzoli et al. 2010). At the

72 conclusion of the SAMOC 3 workshop, it was proposed to instrument and sustain a zonal
73 trans-basin South Atlantic array that will, together with ongoing studies across the two
74 Southern Ocean choke points (Drake Passage and the GoodHope line south of South Africa)
75 and the RAPID/MOCHA array at 26.5°N , provide measurements to evaluate inter-gyre,
76 inter-hemispheric, and inter-ocean connectivity of the MOC (Garzoli et al. 2010).

77 To date, model studies have provided some guidance on a suitable location for a zonal
78 trans-basin *in situ* array in the South Atlantic. A model study by Sime et al. (2006) using
79 the coupled global climate model HadCM3 found that hydrographic sections unsupported by
80 bottom pressure or bottom velocity information or wind information would best reconstruct
81 the MOC around 25°S . Model-based sampling experiments by Baehr et al. (2009) using the
82 global climate model ECHAM5/MPI-OM suggested that 18°S would be a suitable latitude
83 to sample the MOC in the South Atlantic with geostrophic velocity measurement techniques
84 unsupported by bottom velocity information but supported by wind information. However,
85 the ocean component of the coupled models used in those studies were too coarse (horizontal
86 resolution of 1.25° or greater) to adequately resolve western boundary currents. A yet unpub-
87 lished study by researchers at the University of Southampton using both a coarse ($1/4^{\circ}$) and
88 high ($1/12^{\circ}$) resolution version of the global ocean model OCCAM finds that a geostrophic
89 velocity measurement system, unsupported by bottom velocity measurements but supported
90 by wind information, produced the least biased estimate of the MOC but poorly captured
91 the variability along 25°S , whereas an observing system along 15°S or between 32°S and
92 34.5°S would best capture the MOC variability (E. McDonagh and P. Abrahamsen, personal
93 communication). Due to the large spread in suggested latitudes (15°S to 34.5°S) and the
94 assumed constraint of zero bottom velocity in previous studies, further analysis is needed to

95 determine a suitable latitude for a South Atlantic array.

96 In this paper, numerical simulations from two ocean general circulation models, the Par-
97 allel Ocean Climate Model (POCM) and the Ocean general circulation model For the Earth
98 Simulator (OFES), are used to test the ability of *in situ* geostrophic velocity measurement
99 systems supported by bottom velocity information and wind information to observe the
100 MOC and MHT in the South Atlantic. Geostrophic velocity measurement techniques are
101 horizontally integrating by nature, whereas a “picket fence” of direct velocity measurements
102 and bottom pressure recorders require that moorings be spaced closer than zonal decorrela-
103 tion length scales and as such are logistically unfeasible for a fully resolved basin-wide array.
104 Model sampling experiments are conducted to test whether five latitudes, 15°S, 20°S, 25°S,
105 30°S, and 34.5°S (black lines in Fig. 1), are well suited for the deployment of a basin-wide
106 South Atlantic array. The southernmost latitude 34.5°S is the southern boundary of the At-
107 lantic and samples across the southward flowing Brazil Current, northward flowing Benguela
108 Current and Agulhas Eddy corridor in both models, and the northernmost latitude 15°S is
109 well outside of the equatorial waveguide and samples across the northward flowing North
110 Brazil Current in both models (Fig. 1b). These five latitudes are also examined because
111 they encompass locations suggested as suitable for an array in previous studies, or coincide
112 with existing observing systems: 30°S (CLIVAR A10 trans-basin hydrographic sections)
113 and 34.5°S (quarterly AX18 high-density XBT sections since 2002, and two pilot arrays of
114 PIES/CPIES deployed near western and eastern boundaries by an international consortium
115 including the United States, France, Argentina, South Africa, and Brazil).

116 The paper outline is as follows: A description of the models and the method used to
117 reconstruct the MOC and MHT signals with virtual arrays deployed within those models is

118 provided in section 2. The temporal and meridional scales of variability of the MOC and
119 MHT and their interrelation are explored in section 3. In section 4, the ability to reconstruct
120 these signals with geostrophic measurement techniques (i.e. dynamic height moorings with
121 near-bottom velocity and pressure measurements) is examined. Such moorings are expensive,
122 and in section 5, the ability to sample the MOC and MHT with CPIES is tested. In section
123 6, realistically-sized arrays (e.g., reasonable number of sites) are examined that build upon
124 the existing sites from 34.5°S pilot arrays. Finally, in section 7, the results are discussed and
125 summarized.

126 **2. Models and Method**

127 *a. Models*

128 Fields from two global eddy-permitting to eddy-resolving ocean simulations, POCM and
129 OFES, are used to characterize the South Atlantic MOC and MHT. Both models reproduce
130 most of the important aspects of the South Atlantic circulation with adequate realism (e.g.,
131 Fig. 1 shows the similarity between mean POCM and OFES meridional currents at 200 *m*
132 depth), but they vary in the scales they resolve and in the complexity of their numerical
133 schemes. While no model is perfect, concurrent analysis of two different simulations will
134 reduce the uncertainties associated with using only one of them and additionally reveals
135 whether geostrophic velocity measurement systems can capture two different realizations of
136 volume and heat transport.

137 POCM 4C (hereafter POCM) is an implementation of the Semtner/Chervin primitive

138 equation, hydrostatic, z-level model (Semtner et al. 1992; Stammer et al. 1996; Tokmakian
139 and Challenor 1999). The model equations have been discretized in a Mercator B-grid with a
140 nominal horizontal resolution of $1/4^\circ$ and 20 vertical z levels. POCM was forced with daily
141 atmospheric fluxes from the European Center for Medium Weather Forecast (ECMWF)
142 reanalysis starting from 1979 to 1994, and with operational ECMWF data sets until 1998
143 (Tokmakian and Challenor 1999). Although the full integration period was 19-years, only the
144 last twelve years (1986-1997) are analyzed here (similar to Matano and Beier 2003; Schouten
145 and Matano 2006; Baringer and Garzoli 2007; Garzoli and Baringer 2007; Fetter and Matano
146 2008). POCM results are available as 3-day averages every 9-days.

147 OFES is a massively-parallelized implementation of version 3 of the NOAA/GFDL Mod-
148 ular Ocean Model (MOM3) run by Japan Agency for Marine-Earth Science and Technology
149 (JAMSTEC). The model equations have been discretized in a Mercator B-grid with a hor-
150 izontal resolution of 0.1° and 54 vertical z levels. Note, model fields were provided by
151 JAMSTEC at 0.2° increments (every other horizontal grid point). The simulation used in
152 this study was spun up for 50-years with a monthly climatology derived from NCEP/NCAR
153 reanalysis atmospheric fluxes (Masumoto et al. 2004), and then forced with daily mean
154 NCEP/NCAR reanalysis data from 1950 to 2007 (Sasaki et al. 2008). Results are analyzed
155 for the same twelve years as the POCM simulation. OFES results are available as snapshots
156 at 3-day intervals.

157 POCM has been compared against available observations (Stammer et al. 1996; Tok-
158 makian and Challenor 1999; Matano and Beier 2003; Schouten and Matano 2006; Fetter
159 and Matano 2008) and has well-known strengths and weaknesses. Matano and Beier (2003)
160 found that large-scale circulation patterns reproduced by POCM agree well with those in-

161 ferred from hydrographic observations, except in the southeastern Atlantic at intermediate
 162 and deep levels. The path of the Agulhas rings in POCM are in close agreement with the
 163 path inferred from altimetric data, however eddy shedding is too infrequent in the model
 164 (Matano and Beier 2003). POCM successfully simulates the low-frequency variability of
 165 the ACC and the Malvinas Current, but it does not reproduce the correct location of the
 166 Brazil-Malvinas Confluence (Fetter and Matano 2008).

167 While output from OFES has contributed to many studies in the Pacific ocean, to date
 168 few published studies have looked at its behavior in the South Atlantic (Masumoto 2010;
 169 and references therein). OFES reproduces well the large-scale SSH variability in the South
 170 Atlantic compared with altimetric data (Dong et al. 2011; E. Giarolla, personal commu-
 171 nication). However, OFES underestimates the quasi-decadal increasing tendency of SSHA
 172 observed in the South Atlantic (E. Giarolla, personal communication), and the Agulhas rings
 173 are too energetic and the Agulhas ring corridor extends too far to the north in the model
 174 (Dong et al. 2011; E. Giarolla, personal communication).

175 *b. MOC and MHT calculation*

176 Fields from both model simulations are used to construct estimates of the maximum
 177 northward volume transport in the upper limb of the overturning circulation (i.e., the MOC)
 178 and total MHT. The strength of the MOC is given by

$$MOC(t) = \int_{z=-D(t)}^{z=0} dz \int_{x=x_W}^{x=x_E} dx (v(t; x, z) + v_e(t)), \quad (1)$$

179

180 where $D(t)$ is the mid-ocean depth at which the basin-wide integrated volume transport
 181 switches from northward to southward (at approximately 1200 m in OFES and approximately
 182 1500 m in POCM), $v(t; x, z)$ is the model meridional current, and $v_c(t)$ is a spatially uniform
 183 constant applied to give zero net volume transport (as described in Hall and Bryden 1982;
 184 Hirschi et al. 2003; Baehr et al. 2004). Total MHT is computed as

$$Q(t) = \int_{z=z_{btm}}^{z=0} dz \int_{x=x_W}^{x=x_E} dx \rho c_p T(t; x, z) v(t; x, z) \quad (2)$$

185

186 where $\rho = \rho(S, T, p)$ and $c_p = c_p(S, T, p)$ are computed from UNESCO (1983) equations
 187 of state using $S(t; x, z)$ and $T(t; x, z)$ from the model simulations and p evaluated at each
 188 model z-level. Note that the heat transport itself is not mass balance corrected (J. Hirschi,
 189 personal communication).

190 *c. MOC reconstruction with geostrophic velocity measurement techniques*

191 The zonal trans-basin arrays deployed within the high-resolution ocean simulations are
 192 assumed to provide geopotential height anomaly profiles (Φ_{array}) at every zonal grid point.
 193 Geostrophic velocity is then computed, $v_{g,array} = f^{-1} \partial \Phi_{array} / \partial x$, and used to reconstruct the
 194 MOC and MHT. Conceptually, this approach is similar to sampling experiments conducted
 195 by Hirschi et al. (2003) and Baehr et al. (2004) in the North Atlantic, and more recently
 196 by Baehr et al. (2009) in the South Atlantic. However, here the assumption of zero bottom
 197 velocity is relaxed, and reconstructions are compared from geopotential height anomalies
 198 derived from two different measurement techniques. First, model T, S profiles are directly

199 used to calculate geopotential height anomalies ($\Phi_{T,S}$) simulating the use of dynamic height
 200 moorings (e.g., Hirschi et al. 2003; Baehr et al. 2004; Baehr et al. 2009). Second, model
 201 T, S profiles are used to calculate a vertical sound speed profile, which is then integrated to
 202 obtain vertical acoustic travel time. Travel time is then related through look-up tables to
 203 geopotential height anomaly profiles (Φ_{CPIES}), simulating the use of CPIES. This indirect
 204 method is described in more detail in section 2d.

205 For both measurement systems, the reconstructed MOC is given by

$$MOC_{array}(t) = \int_{z=-D_{array}(t)}^{z=0} dz \int_{x=x_W}^{x=x_E} dx v'_{array}(t; x, z) \quad (3)$$

206

207 where

$$v'_{array}(t; x, z) = v_{g,array}(t; x, z) + v_b(t; x, z_{btm}) + v_{Ek}(t; x, z \geq -D_{Ek}) + v_{c,array}(t). \quad (4)$$

208

209 and is the sum of geostrophic velocity ($v_{g,array}$), bottom velocity (v_b), Ekman velocity (v_{Ek}),
 210 and the “zero-net-volume-transport” velocity correction ($v_{c,array}$), respectively. Only $v_{g,array}$
 211 and $v_{c,array}$ vary depending on the use of $\Phi_{T,S}$ versus Φ_{CPIES} . Ekman transport is computed
 212 from the wind stress fields used to force each model simulation, and is evenly distributed in
 213 the upper 50 m ($D_{Ek} = 50$ m).

214 In previous sampling studies, the assumption of zero bottom velocity $v_b(t) = 0$ led to
 215 errors in reproductions of the strength and variability of the MOC along latitudes with
 216 strong bottom trapped currents (Baehr et al. 2004; Baehr et al. 2009). Therefore, any

217 planned geostrophic velocity measurement system in the South Atlantic will make direct
218 near-bottom velocity measurements with current meters 50 m above the seafloor and measure
219 time-varying barotropic flow variations with bottom pressure recorders. For simulations of
220 full trans-basin arrays in sections 4 and 5, v_b is taken directly from the model velocities at the
221 greatest common depth between adjacent geopotential height anomaly profiles to reference
222 the geostrophic velocity shear. For simulations of realistically-sized arrays where the spacing
223 between moorings may exceed zonal decorrelation length scales in section 6, currents are
224 zonally averaged between sites at the shallowest common depth level. This zonal-averaging
225 simulates the type of information that zonal differences of bottom pressure data would
226 provide about the time-varying barotropic flow combined with leveling/referencing by direct
227 velocity measurements made near the base of the moorings (e.g., Johns et al. 2008). Velocity
228 in cross-sectional area that lies below greatest common depth level is filled in with velocity
229 from the adjacent offshore site and integrated over the “bottom triangle”.

230 It should be noted that, as with previous array evaluation studies (e.g., Hirschi et al.
231 2003, Baehr et al. 2004, Baehr et al. 2009) not all aspects of the observing system design
232 are being tested here. Evaluating different vertical distributions of “sensors” on a mooring
233 and vertical blow-down of a mooring (both of which would require models with much finer
234 vertical resolution), pressure sensor drift, and measurement errors are beyond the scope of
235 this paper. Instead the focus is testing how well velocities computed from direct and indirect
236 geostrophic-techniques can reconstruct the MOC and MHT.

237 *d. Estimation of geopotential height anomalies from virtual CPIES*

238 Vertical acoustic travel times τ computed from model hydrography are combined with
239 look-up tables to produce time series of specific volume anomalies δ at each zonal gridpoint.
240 Conceptually, this is similar to the way time series of δ profiles are obtained from CPIES
241 deployed in the real ocean (Meinen and Watts 2000; Watts et al. 2001; Meinen et al. 2004;
242 Meinen et al. 2006), with the difference of perfect knowledge of the model hydrography right
243 at each grid point over the twelve year study period rather than hydrography from a limited
244 number of CTD profiles spread throughout the study region. To construct the $\delta(\tau, p)$ look-
245 up tables, δ profiles computed from model hydrography are sorted by their corresponding τ
246 value and objectively mapped onto a uniform grid with 0.1 *ms* spacing, assuming a Gaussian
247 covariance with a correlation length scale of 5 *ms* and a noise-to-signal energy ratio of 0.01
248 (Bretherton *et al.* 1976). Fig. 2a shows a sample $\delta(\tau, p)$ look-up table in OFES at a gridpoint
249 on the western boundary, 34.5°S, 48°W. Using the table, a time series of δ_{CPIES} profiles is
250 generated at this particular location. Fig. 2b shows the scatter of δ about δ_{CPIES} as a
251 function of travel time at 500 *db*. Integration of the δ_{CPIES} profiles with respect to pressure
252 yields geopotential height anomaly profiles Φ_{CPIES} (Fig. 2c) from which $v_{g,CPIES}$ is then
253 computed. Look-up tables are also constructed for $T(\tau, p)$ and $S(\tau, p)$ for the heat flux
254 reconstructions.

255 *e. MHT reconstruction with geostrophic velocity measurement techniques*

256 The reconstructed MHT is similar for the two arrays

$$Q_{array}(t) = \int_{z=z_{btm}}^{z=0} dz \int_{x=x_W}^{x=x_E} dx \rho c_p T(t; x, z) (v_{g,array}(t; x, z) + v_b(t; x, z_{btm})) + Q_{Ek}(t). \quad (5)$$

257

258 Here, it is assumed that there is perfect knowledge of the temporal evolution of T, S (and
 259 hence ρ and c_p) for $Q_{T,S}$ calculation, whereas T, S are reconstructed from look-up tables for
 260 the Q_{CPIES} calculation. Ekman heat transport, $Q_{Ek}(t)$, is computed using temperatures
 261 vertically averaged in the upper 50 m, and is evenly distributed in the upper 50 m.

262 **3. Model MOC and MHT**

263 *a. MOC*

264 The MOC time series calculated using (1) and direct model velocities from OFES and
 265 POCM are analyzed here. The MOC time series are quite consistent between OFES and
 266 POCM on annual to quasi-decadal timescales at all five latitudes (left panels of Fig. 3 and
 267 Table 1). Note that a 9-month frequency-domain low-pass filter was applied to the time
 268 series to focus on climate relevant time scales. The mean MOC strength ranges between
 269 15.0 to 16.5 Sv (Table 1). In both models, northward transport increases by approximately
 270 1 Sv from 34.5°S to 15°S. This increase in overturning strength from higher to lower lati-
 271 tudes is generally consistent with overturning transports inferred from global inversions of
 272 WOCE hydrographic sections, acknowledging the inversions have order 3 Sv error bars (e.g.,
 273 Ganachaud 2003; Lumpkin and Speer 2007). In OFES, however, this increase is not mono-
 274 tonic, specifically there is a 0.5 Sv decrease in transport from 25°S to 20°S due to southward

275 flow in the semi-enclosed basin between the Brazilian coast and the Vitória-Trindade ridge
276 (Fig. 1). Except at those two latitudes, inter-model biases are less than $0.2 Sv$ (Table 1).
277 The right panels of Fig. 3 show that below the level of the maximum MOC transport (e.g.,
278 below 1500 m) the structure of the time-mean volume transport, $G_V(z)$, is very different
279 between the two simulations. This is due to the relatively weak inflow of Antarctic Bottom
280 Water in POCM that was previously diagnosed in Schouten and Matano (2006).

281 To examine how the MOC variance is distributed among different time-scales in both
282 the OFES and POCM simulations (Fig. 4), the MOC time series has been partitioned into
283 five distinct frequency bands: high-frequency (HF, periods less than 90 days), semi-annual
284 (SA, 90 to 270 days), annual (A, 270 to 450 days), inter-annual (IA, 450 to 1260 days), and
285 quasi-decadal (QD, periods greater than 1260 days). The total (or unfiltered) variance is
286 also computed for both simulations (circles in Fig. 4a,b).

287 At all latitudes the total MOC variability is larger in OFES compared with POCM, due
288 in part to the different model-archival frequencies and the eddy-resolving nature of OFES vs.
289 eddy-permitting nature of POCM. The latter effect is most pronounced at higher latitudes
290 ($25^\circ S$ to $34.5^\circ S$) where OFES is twice as energetic as POCM due mainly to the more frequent
291 passage of strong Agulhas eddies in OFES. Consistent with this, high-frequency variability
292 accounts for over 60% of the total MOC variance in OFES, but only about 50% of the
293 total variance in POCM (Fig. 4c,d)¹. There is a significant amount of energy at both semi-

¹It has been shown that the 3-day snapshot sampling used by OFES misplaces the portion of the total variance related to the diurnal oscillation into the portion of the total variance related to the mean (Priestley 1981; von Storch et al. 2007), and as such the high-frequency variability shown here is underestimated by the variance associated with the diurnal cycle. Similarly, there may be 3-day variability aliased by the POCM

294 annual and annual time scales (Fig. 4a,b). In POCM, the semi-annual and annual variance
295 are comparable at all latitudes, with more energy at annual time scales only along 15°S,
296 20°S and 34.5°S. In OFES, the annual variance dominates the semi-annual at 30°S and
297 34.5°S. The amplitude of the annual cycle of the MOC in these models is stronger than
298 the amplitude of the MOC annual cycle found by Dong et al. (2009) along 34.5°S from 17
299 XBT transects collected along the AX18 line, but is consistent with the strong amplitude
300 observed at the RAPID/MOCHA array at 26.5°N (Kanzow et al. 2010). Inter-annual and
301 quasi-decadal variability account for less than 6% and 4%, respectively, of the total variance
302 in both models, and is weakest at 30°S and 34.5°S in both models. If this holds true in
303 the real ocean, an accurate representation of the MOC annual cycle will be crucial to assess
304 long-term variations.

305 *b. Meridional heat transport*

306 As was the case for the MOC time series, there is general agreement between the time
307 series of MHT between OFES and POCM on annual to quasi-decadal timescales with mean
308 values between 0.41 *PW* and 0.55 *PW* (left panels of Fig. 5 and Table 2). The mean MHT
309 increases in magnitude from 34.5°S to 15°S. However, the meridional gradient of \overline{Q} is more
310 pronounced in OFES which increases by 0.09 *PW*, while in POCM the increase is 0.04 *PW*
311 (Table 2). Note that Lumpkin and Speer (2007) reported an 0.12 *PW* increase in MHT
312 from 0.62 ± 0.15 *PW* at 32°S to 0.74 ± 0.36 *PW* at 11°S using inversions of hydrographic
313 sections. The weak meridional gradient of \overline{Q} in POCM and bias between the two models at

temporal sampling.

314 higher latitudes (right panels of Fig. 5 show $G_H(z)$ the time-mean of vertically integrated
315 meridional heat transport) are due to the weaker meridional cell below the North Atlantic
316 Deep Water cell (right panels of Fig. 3).

317 The distribution of MHT variance into different frequency bands is similar to the MOC
318 variance breakdown shown in Fig. 4. This is evident from the high correlation between
319 MHT and the MOC at all time scales considered here (Fig. 6a,b and Table 3). For example,
320 when high-frequency and semi-annual time scales are excluded the correlation between MHT
321 and the MOC ranges from 0.87 to 0.96 (Table 3). When Q is regressed onto the MOC
322 strength, a robust linear relationship is found for all latitudes (Fig. 6c,d and Table 3). This
323 relationship only begins to deteriorate on quasi-decadal time scales. At 34.5°S , the slope
324 is around 0.05 PWSv^{-1} for high-frequency to inter-annual time scales. These correlations
325 and slopes are consistent with XBT based estimates along 34.5°S where a correlation of
326 0.76 and slope of $0.05 \pm 0.01 \text{ PWSv}^{-1}$ were found (Dong et al. 2009). Linear regressions
327 of the RAPID/MOCHA array data at 26.5°N reveal comparable slopes of 0.079 PWSv^{-1}
328 when MHT was regressed onto the total MOC and 0.064 PWSv^{-1} when Ekman variability
329 is removed prior to the regression (Johns et al. 2011).

330 4. Geostrophic estimation of the MOC and MHT

331 The MOC and MHT are first reconstructed using the full model T, S profiles at every
332 zonal and vertical gridpoint ($MOC_{T,S}$ and $Q_{T,S}$, respectively) and compared with the “true”
333 MOC and Q from section 3 to test along which latitudes geostrophic-type measurements will
334 be most successful. The left panels of Fig. 7 demonstrate the skill of the MOC reconstructions

335 on annual to quasi-decadal time scales for OFES (black solid line) and POCM (blue solid
336 line). The geostrophic technique applied to OFES is able to reproduce the mean MOC
337 (compare black dashed and solid lines in Fig. 7a), with mean differences at five latitudes
338 smaller than $\pm 0.7 Sv$ (black solid line in Fig. 7c). In contrast, the geostrophic technique
339 has difficulty reconstructing the mean MOC in POCM at some latitudes due to weak mean
340 ageostrophic currents on the western boundary (compare blue dashed and solid lines in
341 Fig. 7a), with biases as large as $1.4 Sv$ at $30^\circ S$ (blue solid line in Fig. 7c). Note that these
342 departures from geostrophy may simply be an artifact of using 3-day averages of POCM T, S
343 in the nonlinear dynamic height anomaly calculation.

344 In terms of accurately reproducing the variability of the MOC, the standard deviation
345 of the difference between $MOC_{T,S}$ and MOC is smaller than $1 Sv$ everywhere for both
346 simulations (Fig. 7e) and the correlation between $MOC_{T,S}$ and MOC is always greater than
347 0.9 (Fig. 7g). The reconstructions improve (i.e., lower standard deviation difference and
348 slightly higher correlation) at higher latitudes where the Coriolis parameter is larger. In
349 general, the reconstructions yield better results in OFES than in POCM (compare black
350 and blue lines Fig. 7e,g).

351 The geostrophic technique applied to OFES is able to reproduce the mean MHT (compare
352 black dashed and solid lines in Fig. 7b) with biases of $0.01 PW$ at $34.5^\circ S$ and approximately
353 $0.07 PW$ elsewhere (black solid line in Fig. 7d). In POCM, however, the geostrophic tech-
354 nique produces significantly biased estimates of MHT with biases larger than $\pm 0.10 PW$ at
355 $20^\circ S$, $30^\circ S$, and $34.5^\circ S$ (blue solid line in Fig. 7d). Because the MHT calculation is nonlinear
356 and some temperature fluctuations may be uncorrelated with geostrophic currents, there is
357 slightly less skill in the $Q_{T,S}$ reconstructions (Fig. 7f,h). The standard deviation of the dif-

358 ference between $Q_{T,S}$ and Q is fairly uniform in both models with values of around $0.03 PW$
359 in OFES and $0.07 PW$ in POCM, with the outlier being a standard deviation of $0.11 PW$
360 at $15^\circ S$ in POCM (Fig. 7f). Correlation between $Q_{T,S}$ and Q is everywhere larger than 0.65 ,
361 increases towards higher latitudes, and is larger in OFES than in POCM (Fig. 7h). Note that
362 as expected, the spatial sampling at every other grid point of OFES fields (see section 2a)
363 does not appreciably reduce the skill of the MOC or MHT reconstructions from geostrophic
364 estimation techniques.

365 5. Simulating a CPIES measurement array

366 In the preceding section, it was established that the geostrophic estimation technique
367 works well at all five latitudes and is able to reproduce the variability on annual to quasi-
368 decadal time scales in both models. These initial tests are idealized, however, in the sense
369 that they imply an array of perfect T, S measurements at every horizontal and vertical grid
370 point. As such, the results from the preceding section provide a “best case” test of the
371 performance for an array of dynamic height moorings (T, S array) of the type used in the
372 RAPID/MOCHA array (e.g., Fig. 1b in Johns et al. 2008). In this section, we consider
373 whether transports can be reconstructed using a trans-basin array of the more cost-effective
374 CPIES. Because the narrative is similar for the OFES and POCM simulations (e.g., Table 4
375 compares signal-to-noise ratios of the CPIES reconstructions in both models), hereafter only
376 results from the OFES analysis are discussed.

377 For both the T, S and CPIES array, geostrophic currents have similar means ($\bar{v}_{g,TS} \approx$
378 $\bar{v}_{g,CPIES}$) and the same Ekman currents and bottom currents are applied in (4). Hence, the

379 bias between MOC_{CPIES} and MOC is essentially the same as for the T, S array (compare
380 gray solid and black dashed lines in Fig. 8a). The MHT calculation in (5) is nonlinear and
381 T, S are reconstructed from look-up tables. Consequently, the mean bias between Q_{CPIES}
382 and Q does differ from that of the T, S array but is fairly uniform (0.05 PW) across the five
383 latitudes (compare gray solid and black dashed lines in Fig. 8b).

384 In terms of variability, the standard deviation of $MOC_{CPIES} - MOC$ (black dashed
385 line in Fig. 8c) is about 1.4 Sv between 34.5°S and 20°S and increases to 2.4 Sv at 15°S.
386 Although much larger than the standard deviation of the difference $MOC_{T,S} - MOC$ (gray
387 solid line in Fig. 8c), at 30°S and 34°S the signal-to-noise ratio (ratio of MOC standard
388 deviation to the standard deviation of $MOC_{CPIES} - MOC$) is greater than 2 (Table 4). In
389 contrast, the standard deviation of $Q_{CPIES} - Q$ is about 0.15 PW between 34.5°S and 20°S
390 and jumps to 0.32 PW at 15°S (black dashed line in Fig. 8d) and the signal-to-noise ratio
391 (ratio of Q standard deviation to the standard deviation of $Q_{CPIES} - Q$) is only greater
392 than 1 at 30°S and 34.5°S (Table 4). The correlation between MOC_{CPIES} and MOC is
393 smaller than between $MOC_{T,S}$ and MOC (Fig. 8e). There is, however, a clear preference
394 for higher latitudes, with correlation of approximately 0.9 at 30°S and 34.5°S. Correlations,
395 are significantly lower for MHT, with values around 0.6 at 30°S and 34.5°S (black dashed
396 line in Fig. 8f). Note that MHT derived from MOC_{CPIES} using the empirical relationship
397 between MHT and the MOC discussed in section 3b provides a better estimate of MHT that
398 approaches the skill of $Q_{T,S}$ with correlation of approximately 0.85 at 30°S and 34.5°S (not
399 shown).

400 The reason why the full trans-basin CPIES array is not as successful as the full T, S array
401 is illustrated by Fig. 9. The top panel shows the dynamic range (temporal maximum minus

402 the temporal minimum) of OFES geopotential height anomalies relative to 1000 db (solid
403 lines in Fig. 9a). Along each latitude, there are several regions where the range of geopotential
404 height anomalies is very small (e.g., dashed lines show where range equals $3 \text{ m}^2 \text{ s}^{-2}$ for each
405 latitude). These curves are very similar to the dynamic range of vertical acoustic travel times
406 that would be measured by CPIES, and the low signal areas coincide with regions where the
407 performance of the CPIES methodology is poor in the model. Thus, cross-basin integrations
408 of $v_{g,CPIES}$ will be hampered by these regions of lower skill. Note that the dynamic range
409 of the meridional component of the OFES geostrophic velocity mirrors the curves in Fig. 9a
410 (not shown).

411 Fig. 9a provides additional information useful for the design of a realistically-sized ar-
412 ray. First, the dynamic range is largest at higher latitudes (25°S to 34.5°S), consistent with
413 increased skill of the CPIES array at higher latitudes. Second, the signal is mainly concen-
414 trated near the western and eastern boundaries along 34.5°S . The Agulhas ring energy is
415 spread out over a larger area and has moved into the interior for 25°S and 30°S , and as such
416 the variability along these latitudes would be difficult to monitor with a practical number
417 of moorings irrespective of the type of measurement system used. Fig. 9b compares the
418 observed dynamic range of sea surface height anomalies from AVISO from 1992 to 2007 in
419 water deeper than 1000 m. While not precisely the same measurement, the observed lon-
420 gitudinal patterns are very similar to the model dynamic height anomaly patterns, except
421 observed Agulhas ring energy does not extend to 25°S (consistent with Dong et al. 2011; E.
422 Giarolla, personal communication), bolstering the idea that a realistic number of moorings
423 will work better at 34.5°S .

6. Arrays with realistic horizontal resolution

By the various measures described in the previous sections, higher latitudes (in particular 30°S and 34.5°S) were shown to be better for a South Atlantic array comprised of geostrophic-type moorings. Of course instrumenting a trans-basin section with a mooring at every 0.2° of longitude is not feasible; even using CPIES such a dense line of instruments is not reasonable. Given that most of the geopotential height anomaly signal is concentrated near the boundaries along 34.5°S (Fig. 9) and that two small arrays have already been deployed near the boundaries at the nominal latitude of 34.5°S (black stars in Fig. 1a), we test whether realistically-sized arrays could be used to monitor the MOC and MHT along that latitude.

The 34.5°S pilot arrays were primarily established to observe components of South Atlantic circulation (i.e., the boundary currents), but are not yet sufficient for basin-wide integrations of volume and heat transport. When geostrophic-type moorings are deployed within OFES at the pilot array sites, limited information on the western boundary flow and even less information on the eastern boundary flow is captured (Fig. 10b) when compared to the full resolution of the model (Fig. 10a). Likewise only a fraction of the variability is captured with the pilot arrays (compare Fig. 11a,b). Hence, different array configurations of dynamic height moorings or CPIES were tested to determine potential modifications to the pilot arrays (Table 5).

Starting from a uniform 1° degradation of the full array, locations were systematically removed from the interior and the boundaries using MOC and MHT reconstruction skill to determine key locations where instruments should be placed within OFES (e.g., how far they array should extend offshore on the boundaries, how close sites should be to topographic

446 features). Practical constraints such as keeping the number of sites reasonably small were
447 also considered. It was found to be important to place enough sites on the boundaries to
448 ensure that transport variations were adequately resolved, and to also have some sites near
449 topographic features such as Rio Grande Rise, Mid-Atlantic Ridge, and Walvis Ridge (akin
450 to previous studies by Hirschi et al. 2003; Baehr et al. 2004 in North Atlantic). Results are
451 shown for four of the arrays that were tested. These reduced arrays highlight the importance
452 of the interior sites, the western boundary sites, the eastern boundary sites. Note, similar
453 results were found when the four arrays were deployed within POCM, and only results from
454 the OFES analysis are discussed.

455 Array 1 consists of five interior sites near topographic features: one west of Rio Grande
456 Rise near 32°W , one on either side of Mid-Atlantic Ridge near 20°W and 12°W and one
457 on either side of the Walvis Ridge near 6°W and 1°E . In addition, Array 1 has a site on
458 each boundary inshore of the existing pilot array instruments. By design, this array produces
459 weak geostrophic flows on the boundaries (Figs. 10c and 11c). Array 2 populates the western
460 boundary with an additional 7 moorings compared with Array 1 (Table 5), and adequately
461 resolves the structure and variability of the Brazil Current and Deep Western Boundary
462 Current (Figs. 10d and 11d). Array 3 populates the eastern boundary with an additional
463 5 moorings compared with Array 1 (Table 5). Array 3 reproduces the northward flowing
464 Benguela Current and southward return flow to the west of that current, and captures most
465 of Agulhas ring variability (Figs. 10e and 11e). Finally, Array 4 combines Arrays 2 and 3
466 and has a total of 19 moorings (Figs. 10f and 11f).

467 Fig. 12 shows the mean bias, errors in the vertical structure and temporal evolution of the
468 Array 1 to 4 reconstructed transports relative to the “true” transports. Note that errors in

469 the vertical structure are estimated by the standard deviation of the difference between the
 470 time mean of the vertically integrated transports, $G_{V,array} - G_V$ and $G_{H,array} - G_H$ (see Fig. 13
 471 for Array 4 vertical structures). There is a marked difference in the skill of the MOC and
 472 MHT reconstructions for the four different array configurations (Fig. 12). In the model, the
 473 MOC and MHT are strongly correlated with Ekman volume and heat transport. As a result,
 474 even Array 1 has some skill (correlation greater than 0.5). However, it poorly represents
 475 the vertical structure of mean volume and heat transport (Fig. 12c,d) and the standard
 476 deviation of $MOC_{Array\ 1} - MOC$ and $Q_{Array\ 1} - Q$ are large (Fig. 12e,f). Both Arrays 2 and
 477 3 produce negatively and positively biased estimates of the mean transports, respectively, as
 478 they primarily observe only one side of the basin (Fig. 12a,b). They do, however, decrease
 479 the errors in the vertical structure of mean volume and heat transport and the temporal
 480 evolution of the MOC and MHT as evidenced by lowered standard deviations and increased
 481 correlations when compared with Array 1. Putting together information from both western
 482 and eastern boundaries (Array 4) reduces the biases to $-0.7\ Sv$ and $-0.13\ PW$ and the
 483 errors in the vertical structure drop to about $0.6\ Sv$ and $0.03\ PW$ (Fig. 13). Improvements
 484 are made to both the temporal evolution of the reconstructed MOC (standard deviation of
 485 $MOC_{Array\ 4} - MOC$ is less than $2\ Sv$ and the correlation exceeds 0.75) and MHT (standard
 486 deviation of $Q_{Array\ 4} - Q$ is less than $0.15\ PW$ and the correlation exceeds 0.65). For all
 487 four arrays, the MOC and MHT reconstructions have comparable skill whether simulated
 488 dynamic height moorings or CPIES are considered (compare gray solid and black dashed
 489 lines in Fig. 12), because few sites are located in regions where the CPIES methodology
 490 was found to perform poorly (Fig. 9). This suggests that CPIES could be an important
 491 component of a South Atlantic MOC and MHT array.

7. Summary and Conclusions

To ascertain whether the MOC and MHT variability observed in the North Atlantic is local or part of a larger-scale pattern of variability and to understand the origins and dynamics of this variability, a trans-basin observing system is needed in the South Atlantic. While producing relatively unbiased estimates of South Atlantic transports is an important goal, an array that can characterize the short-term (seasonal to inter-annual) variability of those transports will provide a crucial benchmark for assessing long-term variations. Two numerical simulations, POCM and OFES, were used to determine a suitable latitude for an *in situ* geostrophic velocity measurement system for the MOC and MHT in the South Atlantic. Along five latitudes, 15°S, 20°S, 25°S, 30°S and 34.5°S, geopotential height anomaly profiles and geostrophic velocities were computed directly from the model T, S profiles (simulating dynamic height moorings) or indirectly from look-up tables (simulating CPIES).

The two models produced consistent estimates of the mean strength of the MOC and MHT with values increasing by 0.8 to 1 Sv and 0.04 to 0.09 PW , respectively, from 34.5°S to 15°S. Due to different model-archival frequencies and eddy-resolving nature of OFES vs. eddy-permitting nature of POCM, the total MOC and MHT variability in OFES significantly exceeded that of POCM. Once high-frequency and semi-annual time scales were removed, both models exhibited strong annual cycles in phase with the Ekman annual cycles. While this finding was at odds with quarterly XBT estimates of the annual cycles of the MOC and MHT along 34.5°S (Baringer and Garzoli 2007; Garzoli and Baringer 2007; Dong et al. 2009), it was consistent with recent daily time series observations from the RAPID/MOCHA array at 26.5°N in the North Atlantic (Kanzow et al. 2010; Johns et al. 2011). Continuous-

514 in-time measurements are needed to resolve this apparent inconsistency between models and
515 observations, and also to investigate why the annual cycle of geostrophic transports are weak
516 relative to the annual cycle of Ekman transports within models. Despite this disagreement,
517 the linear relationship between the MOC and MHT found in observations (Dong et al. 2009;
518 Johns et al. 2011) was also found for both model simulations.

519 A trans-basin geostrophic array deployed within in OFES was able to reconstruct the
520 mean MOC and MHT, with biases less than $\pm 0.7 Sv$ and $\pm 0.07 PW$ everywhere. In POCM,
521 the geostrophic array was unable to reconstruct the mean MOC and MHT at some latitudes
522 due to weak mean ageostrophic currents on the western boundary. In terms of variability, the
523 idealized geostrophic array accurately reproduced the MOC variability at all five latitudes in
524 both simulations (standard deviation of $MOC_{T,S} - MOC$ smaller than $1 Sv$ and correlation
525 exceeds 0.9) with a slight preference for higher latitudes. Because MHT reconstruction
526 involved a nonlinear calculation and some temperature fluctuations were uncorrelated with
527 geostrophic currents, there was somewhat less skill in the $Q_{T,S}$ reconstructions. However,
528 such a strong relationship exists between MHT and the MOC, that the correlation between
529 $Q_{T,S}$ and Q was still greater than 0.65 everywhere and it increased with higher latitudes.

530 A trans-basin array of CPIES was deployed in OFES and compared against the trans-
531 basin geostrophic array which is an idealization of an array of dynamic height moorings
532 (e.g., no mooring motion, measurement errors, instrument drift, or vertical subsampling).
533 The skill of MOC and MHT reconstructions for the CPIES array deployed within OFES was
534 modest from $15^\circ S$ to $25^\circ S$, but approached that of the idealized geostrophic array at $30^\circ S$ and
535 $34.5^\circ S$. This was only true at $34.5^\circ S$ in POCM (e.g., Table 4). Although these results may
536 be model-dependent, analyses conducted with the high resolution OCCAM simulations also

537 suggest that a geostrophic velocity measurement system deployed between 32°S and 34.5°S
538 would be successful in reproducing the MOC variability (E. McDonagh and P. Abrahamsen,
539 personal communication).

540 Through analysis of the dynamic range of the OFES geopotential height anomalies rela-
541 tively quiescent regions in the interior were identified where the performance of the virtual
542 CPIES was poor, limiting the skill of cross-basin integrations. Most of the OFES geopo-
543 tential height anomaly signal (as well as the actual observed sea surface height anomaly
544 signal) was found at higher latitudes (25°S, 30°S, and 34.5°S). Of those three latitudes, the
545 signal was only concentrated near the boundaries along 34.5°S suggesting that this latitude
546 is well suited for a realistically-sized South Atlantic array. Preliminary analysis of the first
547 18 months of data from the western boundary moorings along 34.5°S shows a roughly similar
548 longitudinal pattern of dynamic range to that seen in OFES (not shown).

549 Reconstructions from four realistically-sized arrays that incorporate sites from the exist-
550 ing pilot arrays along 34.5°S were analyzed in OFES. The largest of the four arrays which
551 consisted of 19 mooring sites (8 on the western boundary, 5 in the interior, and 6 on the
552 eastern boundary) was able to reproduce well the temporal evolution and time-mean vertical
553 structure of the MOC and to a lesser extent the MHT. These four arrays minimally sampled
554 the interior, and as a result, the reconstructions from the simulated dynamic height moor-
555 ings and CPIES had comparable skill. This suggests that CPIES could be an important
556 component of a more balanced South Atlantic array along 34.5°S.

557 Any planned South Atlantic trans-basin array will likely consist of a combination of
558 instruments that will be used to directly (dynamic height moorings combined with current
559 meters and bottom pressure recorders) and indirectly (CPIES/PIES) estimate the variability

560 of the MOC and MHT. Given that there is important mesoscale variability in the South
561 Atlantic, analysis of the mooring data will need to be interpreted in concert with other
562 existing observing systems with better zonal resolution but coarser temporal resolution (e.g.,
563 altimetry, cross-basin XBT transects, and ARGO). These multi-platform comparisons will
564 be required to better understand how the volume and heat transports estimated by the
565 trans-basin array are influenced by mesoscale features and variability. For these reasons,
566 the mooring locations should be strategically placed under JASON and Envisat altimetry
567 groundtracks whenever possible (which may also allow some extension of the analysis to the
568 previous decade). What this study has shown is that, so long as enough sites are located
569 on the western and eastern boundaries and in the interior near key topographic features, a
570 trans-basin array of approximately 20 geostrophic-type moorings can be effectively used to
571 reproduce the temporal evolution and vertical structure of the MOC and MHT along the
572 nominal latitude of 34.5°S .

573 *Acknowledgments.*

574 The authors would like to thank Povl Abrahamsen, Yeun-Ho Daneshzadeh, Gustavo
575 Goni, Joel Hirschi, and Bill Johns for helpful discussions regarding the MOC and MHT
576 reconstructions. We thank Shenfu Dong and Tony Lee for the suggestion to explore the
577 dependence of the MOC and MHT relationship on different time scales. Comments from
578 SAMOC3 Workshop participants (<http://www.aoml.noaa.gov/phod/SAMOC/>) and review-
579 ers improved the manuscript. Thank you to Yoshikazu Sasai, Robin Tokmakian, Corinne
580 James, and Eric Beals for providing output from the OFES and POCM simulations. The
581 AVISO product was produced by the CLS Space Oceanography Division as part of the En-
582 vironment and Climate EU ENACT project (EVK2-CT2001-00117) and with support from
583 CNES. The authors RCP, SLG, and CSM were supported by the NOAA/Atlantic Oceano-
584 graphic and Meteorological Laboratory, and RPM acknowledges NSF grants OCE-0726994
585 and OCE-0928348 and NASA grant NNX08AR40G.

696 **List of Figures**

697 1 Map of a) POCM and b) OFES twelve-year mean meridional velocity at 200 m
698 depth. Lines indicate the five latitudes tested for a potential South Atlantic
699 array: 15°S, 20°S, 25°S, 30°S, and 34.5°S. Black contours indicate the 100,
700 1500, 2000, and 3000 *m* isobaths. Topographic features such as the Rio Grande
701 Rise and the Mid-Atlantic, Walvis, and Vitória-Trindade Ridges are identified
702 in panel a), and the North Brazil, Brazil, and Benguela Currents are identified
703 in panel b). Black stars in panel a) show location of pilot arrays along 34.5°S.
704 Red lines in panel b) delineate approximate boundaries for the Agulhas Eddy
705 corridor. 39

706 2 Example of virtual IES methodology applied to OFES at 34.5°S, 48°W: a)
707 $\delta(\tau, p)$ look-up table, b) scatter of the actual δ values at 500 db about the
708 δ_{CPIES} values (blue line) as a function of τ , and c) comparison of temporal
709 evolution of Φ (black line) and Φ_{CPIES} (blue line) at 500 db. 40

710 3 Left panels: MOC time series (in *Sv*) from the OFES (black line) and POCM
711 (blue line) models at a) 15°S, b) 20°S, c) 25°S, d) 30°S, and e) 34.5°S. Time
712 scales shorter than 9 months have been removed. Right panels: Time-mean
713 of vertically integrated meridional volume transport from $z = 0$ to z , $G_V(z)$,
714 in *Sv*. See Table 1 for additional statistics. 41

715	4	MOC variance (upper) and percentage of total variance (lower) partitioned	
716		into 5 different frequency bands for OFES (left) and POCM (right) at 15°S	
717		(red), 20°S (green), 25°S (blue), 30°S (magenta), and 34.5°S (black). High-	
718		frequency (HF), semi-annual (SA), annual (A), inter-annual (IA), and quasi-	
719		decadal (QD) bands indicate periods less than 90 days, 90 to 270 days, 270 to	
720		450 days, 450 to 1260 days, and greater than 1260 days, respectively. Circles	
721		in panels a) and b) indicate the total unfiltered variance.	42
722	5	Left panels: Meridional heat transport time series (in PW) from the OFES	
723		(black line) and POCM (blue line) models at a) 15°S, b) 20°S, c) 25°S, d)	
724		30°S, and e) 34.5°S. Time scales shorter than 9 months have been removed.	
725		Right panels: Time-mean of vertically integrated meridional heat transport	
726		from $z = 0$ to z , $G_H(z)$, in PW . See Tables 2 and 3 for additional statistics.	43
727	6	a-b) Correlation and c-d) the slope of linear regression between MHT and	
728		MOC transport in 5 different frequency bands for OFES (left) and POCM	
729		(right) at 15°S (red), 20°S (green), 25°S (blue), 30°S (magenta), and 34.5°S	
730		(black). High-frequency (HF), semi-annual (SA), annual (A), inter-annual	
731		(IA), and quasi-decadal (QD) bands indicate periods less than 90 days, 90	
732		to 270 days, 270 to 450 days, 450 to 1260 days, and greater than 1260 days,	
733		respectively.	44

734	7	Reconstruction statistics for the idealized geostrophic (T, S) array deployed	
735		within OFES (black solid line) and POCM (blue solid line) at five latitudes.	
736		Left panels correspond to the MOC reconstruction, and right panels corre-	
737		spond to the MHT reconstruction. Shown here are the a-b) reconstructed	
738		means (dashed line correspond to mean values in Tables 1 and 2), c-d) mean	
739		of $MOC_{T,S} - MOC$ and $Q_{T,S} - Q$, e-f) standard deviation of $MOC_{T,S} - MOC$	
740		and $Q_{T,S} - Q$, g-h) correlation between $MOC_{T,S}$ and MOC and $Q_{T,S}$ and Q .	
741		Time scales shorter than 9 months have been removed.	45
742	8	OFES reconstruction statistics for the idealized geostrophic (T, S) array (gray	
743		solid line) and CPIES array (black dashed line) at five latitudes. Left panels	
744		correspond to the MOC reconstruction, and right panels correspond to the	
745		MHT reconstruction. Shown here are the a-b) mean of $MOC_{array} - MOC$	
746		and $Q_{array} - Q$, c-d) standard deviation of $MOC_{array} - MOC$ and $Q_{array} - Q$,	
747		e-f) correlation between MOC_{array} and MOC and Q_{array} and Q . Time scales	
748		shorter than 9 months have been removed.	46
749	9	a) Dynamic range of OFES geopotential height anomalies (in $m^2 s^{-2}$) along	
750		15°S (red), 20°S (green), 25°S (blue), 30°S (magenta), and 34.5°S (black). b)	
751		Dynamic range of AVISO SSHA (in dm). Values only shown where bottom	
752		depth exceeds 1000 m . An offset is applied from one latitude to the next	
753		(dashed lines show reference value of $3 m^2 s^{-2}$ ($3 dm$) for each latitude). The	
754		thick horizontal bars indicate regions where bottom depth is shallower than	
755		3500 m	47

756	10	OFES mean v_g using density profiles for a) full model resolution, b) the pilot	
757		array, c) Array 1, d) Array 2, e) Array 3, and f) Array 4. Topographic features	
758		such as the Rio Grande Rise and the Mid-Atlantic and Walvis Ridges are	
759		identified in panel a) by the labels A, B, and C, respectively.	48
760	11	Same as Figure 10 except for standard deviation of v_g	49
761	12	OFES reconstruction statistics for the reduced T, S (gray solid line) and re-	
762		duced CPIES (black dashed line) arrays 1 to 4. Left panels correspond to the	
763		MOC reconstruction, and right panels correspond to the MHT reconstruc-	
764		tion. Shown here are the a-b) mean of $MOC_{array} - MOC$ and $Q_{array} - Q$,	
765		c-d) standard deviation of $G_{V,array} - G_V$ and $G_{H,array} - G_H$ (see Fig. 13),	
766		e-f) standard deviation of $MOC_{array} - MOC$ and $Q_{array} - Q$, g-h) correlation	
767		between MOC_{array} and MOC and Q_{array} and Q . Time scales shorter than 9	
768		months have been removed.	50
769	13	A comparison of the OFES a) time-mean vertically integrated meridional	
770		volume transport $G_V(z)$ (thin black line) with volume transport from T, S	
771		Array 4 $G_{V,TS4}$ (gray solid line) and CPIES Array 4 $G_{V,CPIES4}$ (black dashed	
772		line) and b) time-mean vertically integrated meridional heat transport $G_H(z)$	
773		(thin black line) with heat transport from T, S Array 4 $G_{H,TS4}$ (gray solid	
774		line) and CPIES Array 4 $G_{H,CPIES4}$ (black dashed line). Units are in Sv and	
775		PW , respectively.	51

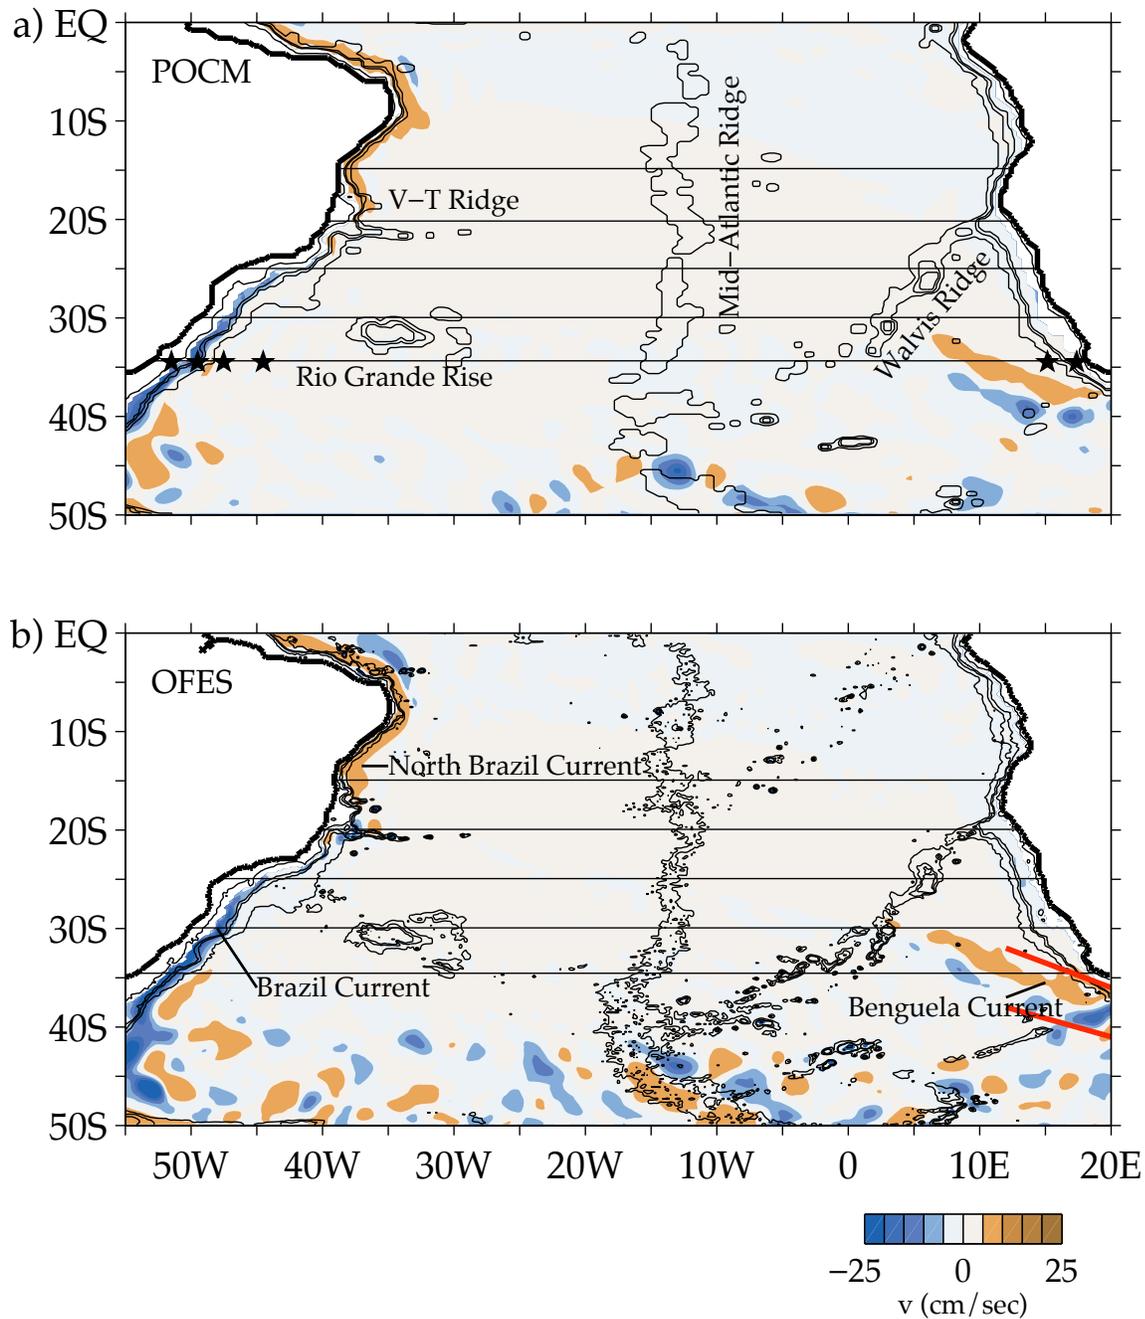

FIG. 1. Map of a) POCM and b) OFES twelve-year mean meridional velocity at 200 m depth. Lines indicate the five latitudes tested for a potential South Atlantic array: 15°S, 20°S, 25°S, 30°S, and 34.5°S. Black contours indicate the 100, 1500, 2000, and 3000 m isobaths. Topographic features such as the Rio Grande Rise and the Mid-Atlantic, Walvis, and Vitória-Trindade Ridges are identified in panel a), and the North Brazil, Brazil, and Benguela Currents are identified in panel b). Black stars in panel a) show location of pilot arrays along 34.5°S. Red lines in panel b) delineate approximate boundaries for the Agulhas Eddy corridor.

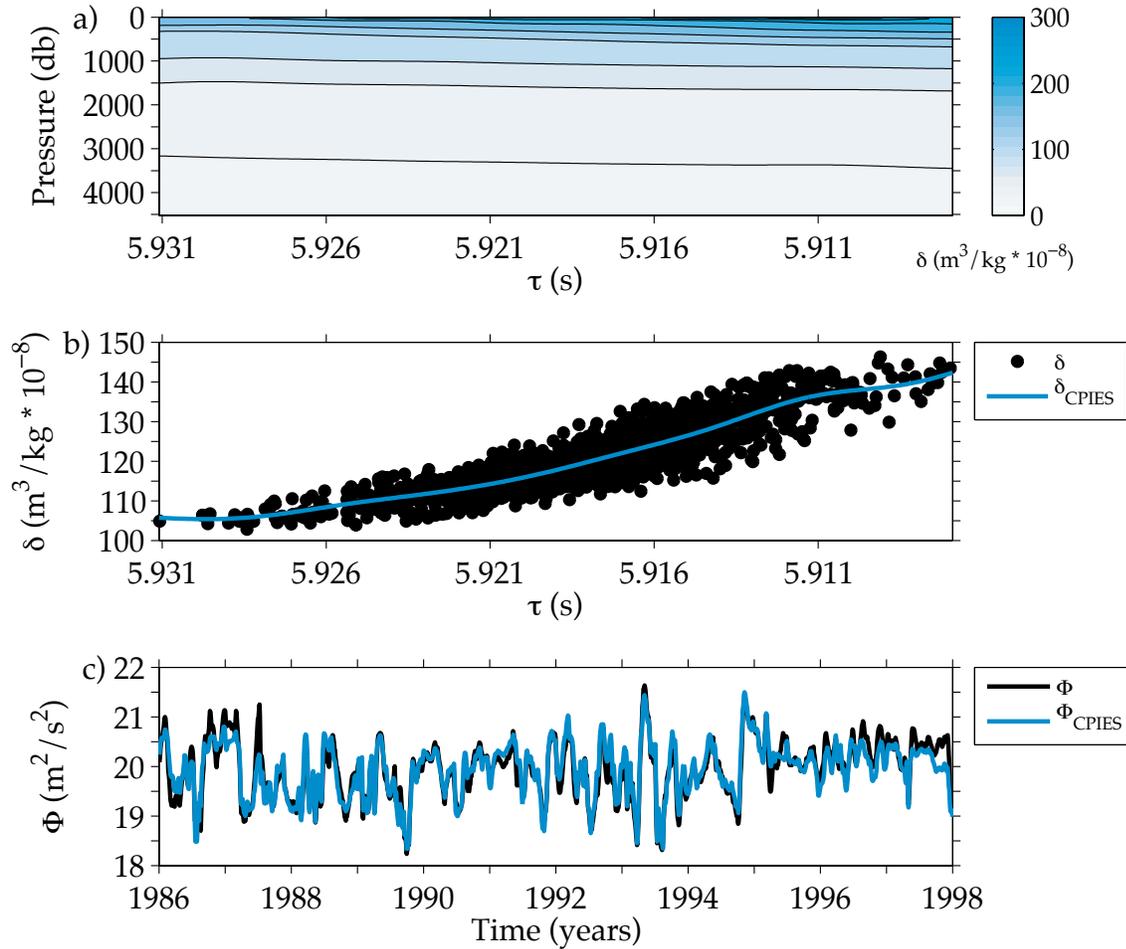

FIG. 2. Example of virtual IES methodology applied to OFES at 34.5°S, 48°W: a) $\delta(\tau, p)$ look-up table, b) scatter of the actual δ values at 500 db about the δ_{CPIES} values (blue line) as a function of τ , and c) comparison of temporal evolution of Φ (black line) and Φ_{CPIES} (blue line) at 500 db.

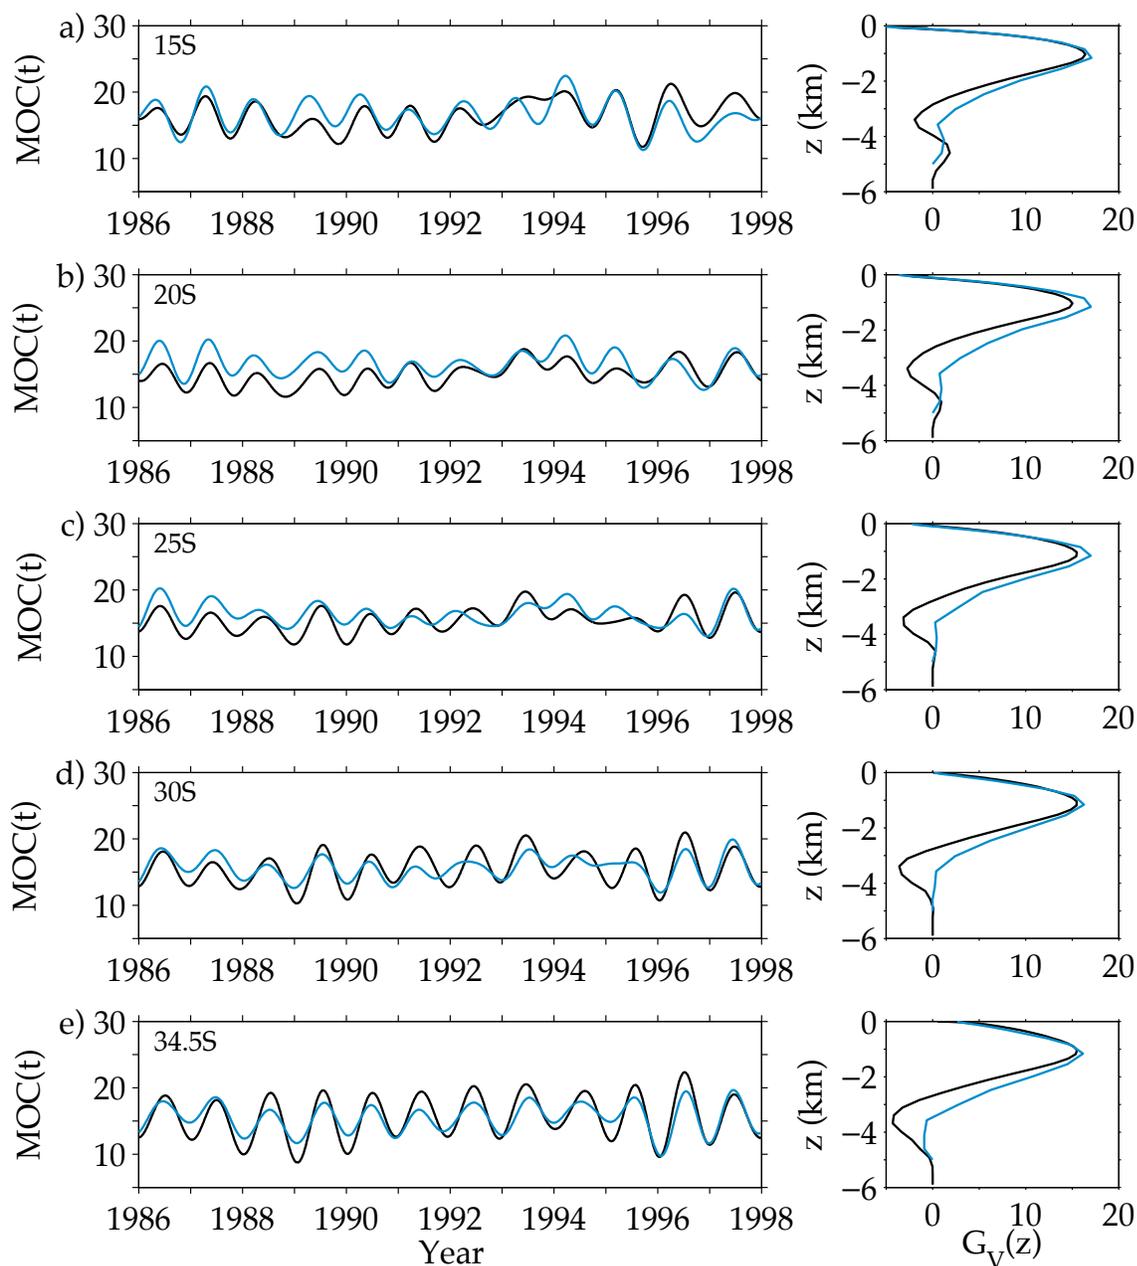

FIG. 3. Left panels: MOC time series (in Sv) from the OFES (black line) and POCM (blue line) models at a) 15°S, b) 20°S, c) 25°S, d) 30°S, and e) 34.5°S. Time scales shorter than 9 months have been removed. Right panels: Time-mean of vertically integrated meridional volume transport from $z = 0$ to z , $G_V(z)$, in Sv . See Table 1 for additional statistics.

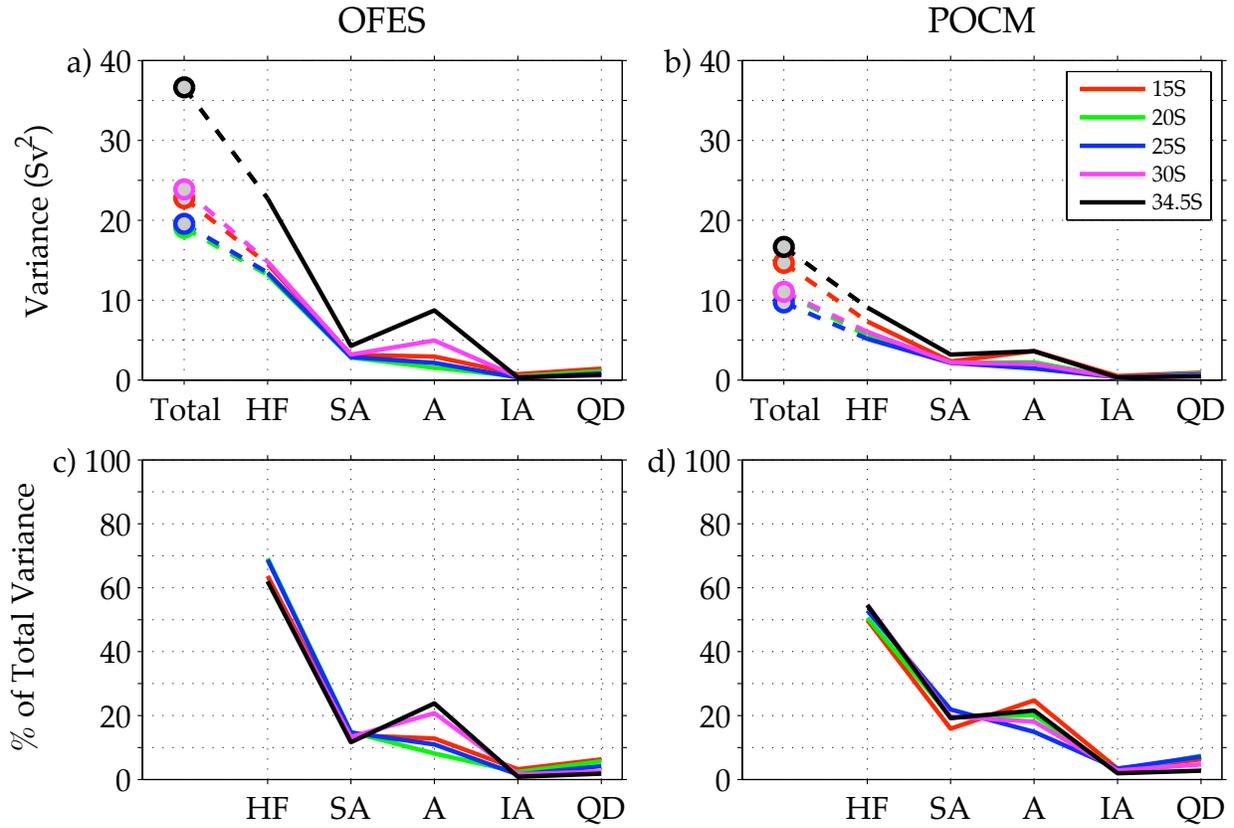

FIG. 4. MOC variance (upper) and percentage of total variance (lower) partitioned into 5 different frequency bands for OFES (left) and POCM (right) at 15°S (red), 20°S (green), 25°S (blue), 30°S (magenta), and 34.5°S (black). High-frequency (HF), semi-annual (SA), annual (A), inter-annual (IA), and quasi-decadal (QD) bands indicate periods less than 90 days, 90 to 270 days, 270 to 450 days, 450 to 1260 days, and greater than 1260 days, respectively. Circles in panels a) and b) indicate the total unfiltered variance.

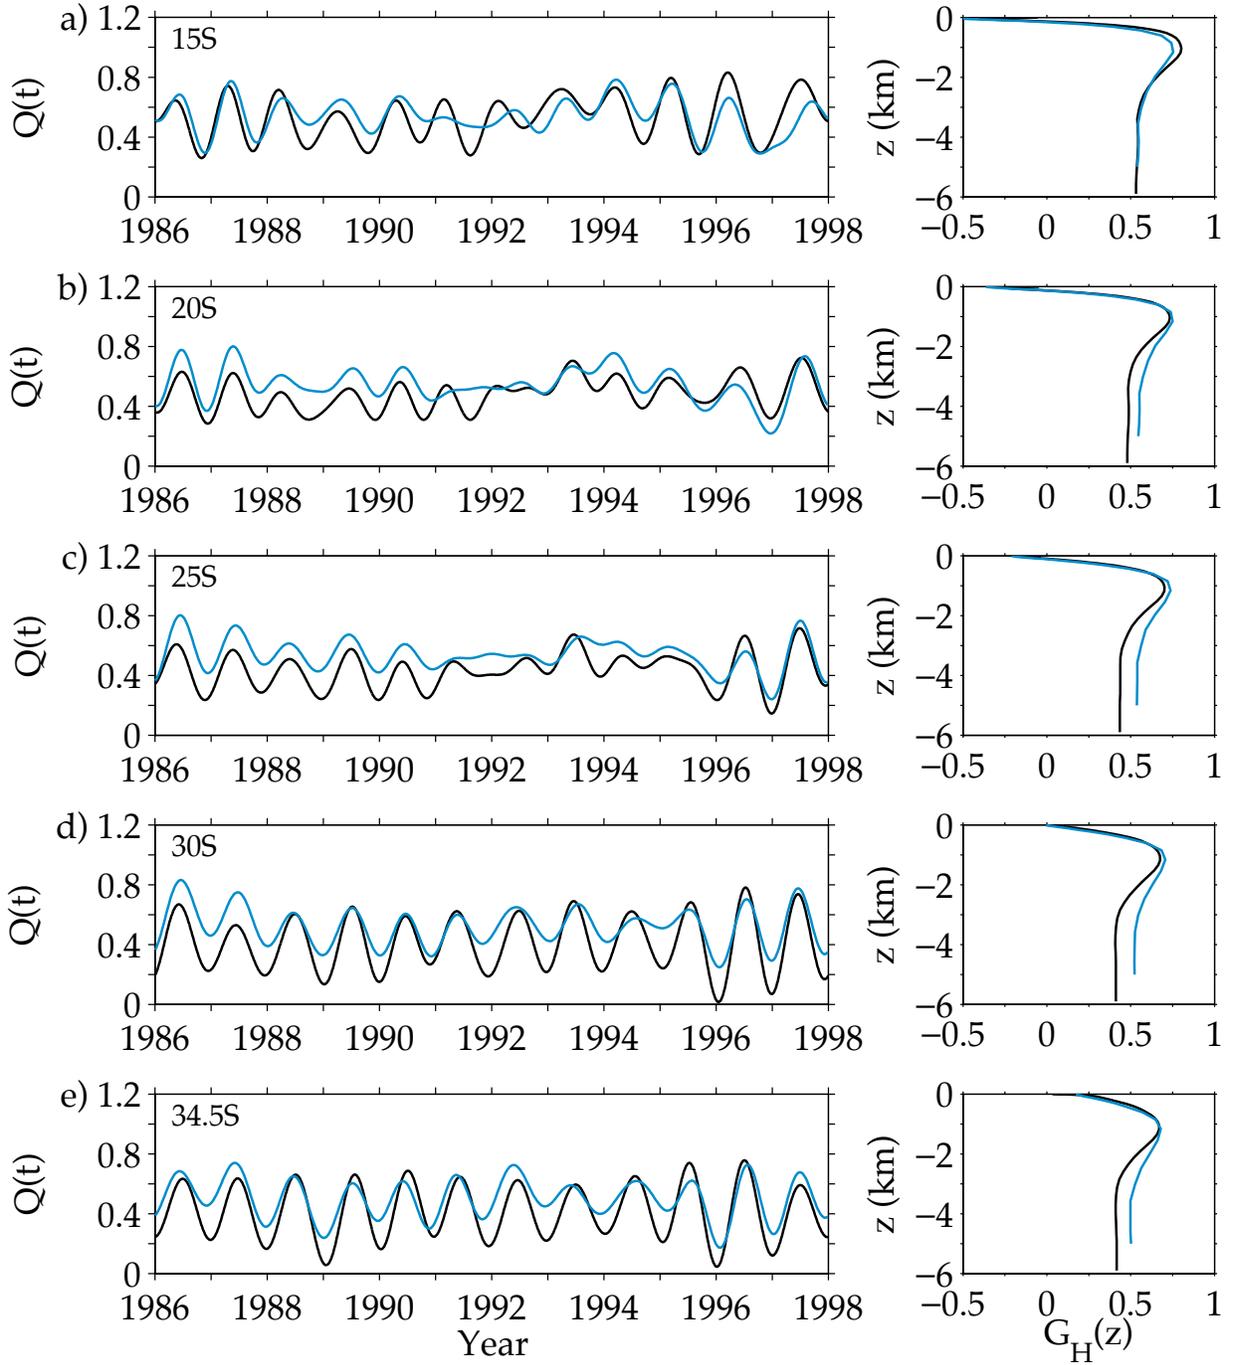

FIG. 5. Left panels: Meridional heat transport time series (in PW) from the OFES (black line) and POCM (blue line) models at a) 15°S, b) 20°S, c) 25°S, d) 30°S, and e) 34.5°S. Time scales shorter than 9 months have been removed. Right panels: Time-mean of vertically integrated meridional heat transport from $z = 0$ to z , $G_H(z)$, in PW . See Tables 2 and 3 for additional statistics.

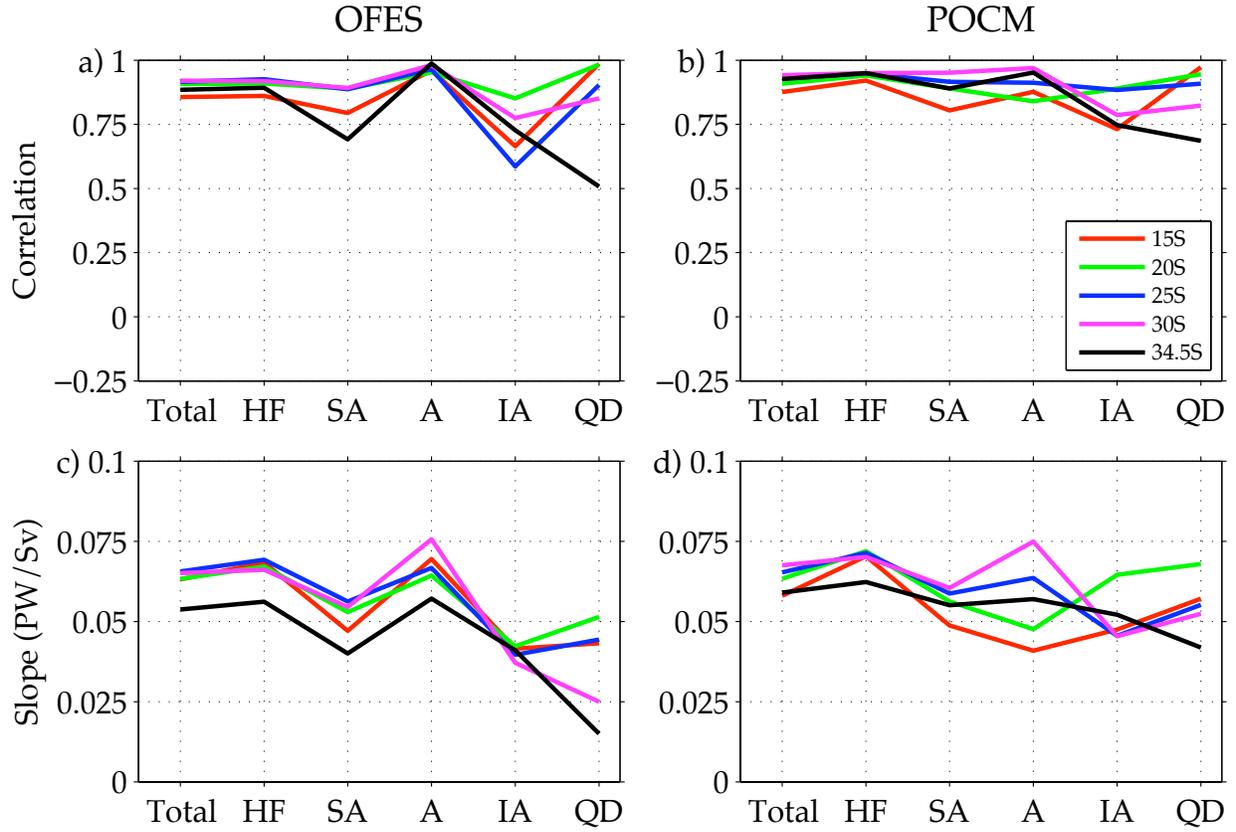

FIG. 6. a-b) Correlation and c-d) the slope of linear regression between MHT and MOC transport in 5 different frequency bands for OFES (left) and POCM (right) at 15°S (red), 20°S (green), 25°S (blue), 30°S (magenta), and 34.5°S (black). High-frequency (HF), semi-annual (SA), annual (A), inter-annual (IA), and quasi-decadal (QD) bands indicate periods less than 90 days, 90 to 270 days, 270 to 450 days, 450 to 1260 days, and greater than 1260 days, respectively.

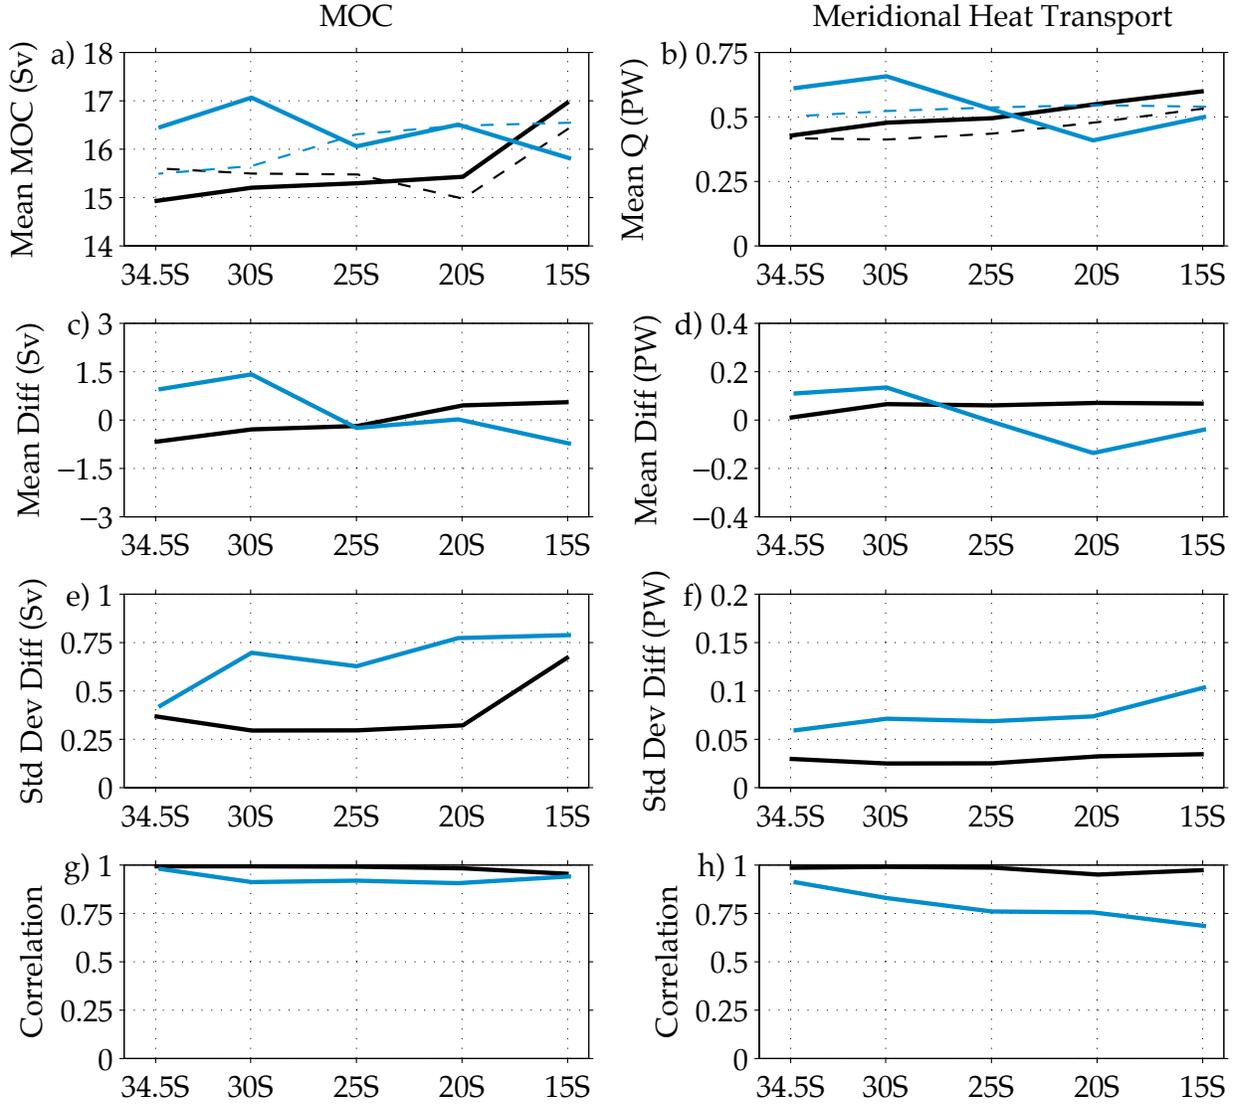

FIG. 7. Reconstruction statistics for the idealized geostrophic (T, S) array deployed within OFES (black solid line) and POCM (blue solid line) at five latitudes. Left panels correspond to the MOC reconstruction, and right panels correspond to the MHT reconstruction. Shown here are the a-b) reconstructed means (dashed line correspond to mean values in Tables 1 and 2), c-d) mean of $MOC_{T,S} - MOC$ and $Q_{T,S} - Q$, e-f) standard deviation of $MOC_{T,S} - MOC$ and $Q_{T,S} - Q$, g-h) correlation between $MOC_{T,S}$ and MOC and $Q_{T,S}$ and Q . Time scales shorter than 9 months have been removed.

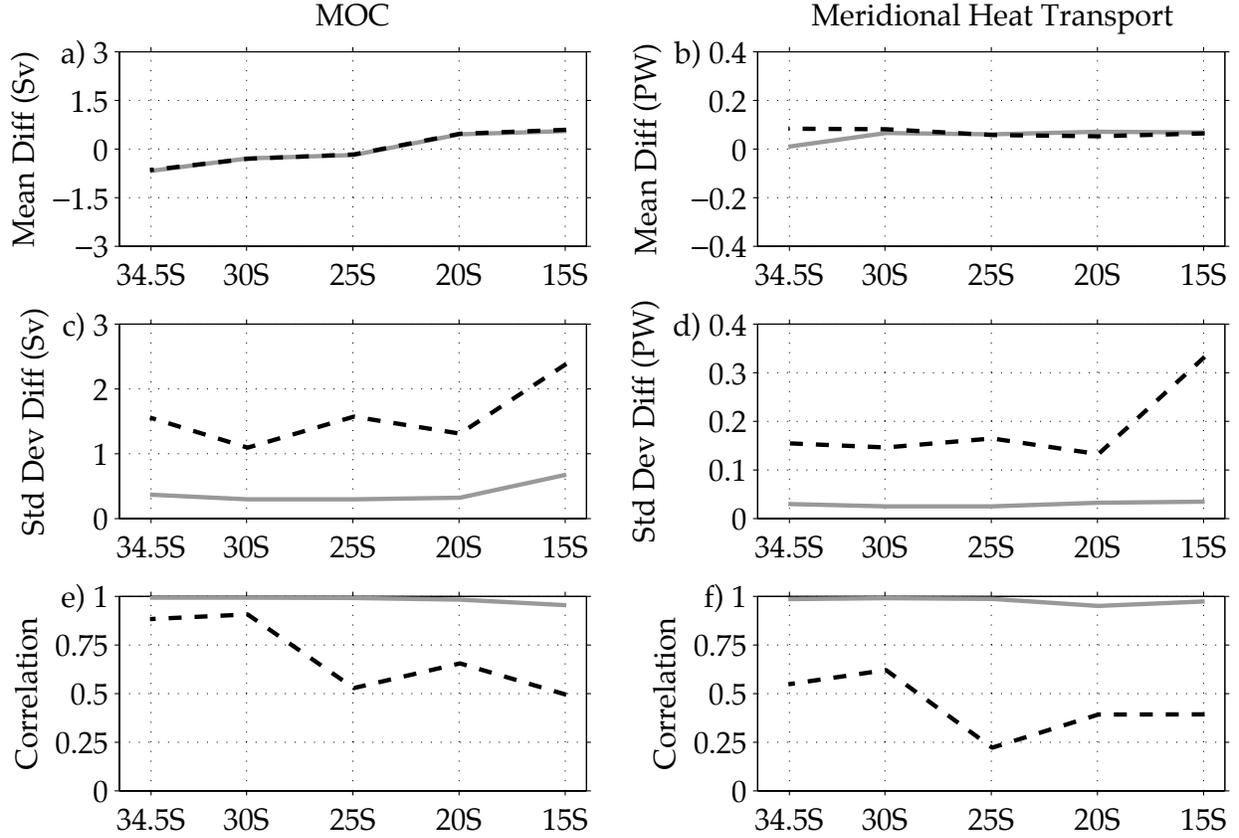

FIG. 8. OFES reconstruction statistics for the idealized geostrophic (T, S) array (gray solid line) and CPIES array (black dashed line) at five latitudes. Left panels correspond to the MOC reconstruction, and right panels correspond to the MHT reconstruction. Shown here are the a-b) mean of $MOC_{array} - MOC$ and $Q_{array} - Q$, c-d) standard deviation of $MOC_{array} - MOC$ and $Q_{array} - Q$, e-f) correlation between MOC_{array} and MOC and Q_{array} and Q . Time scales shorter than 9 months have been removed.

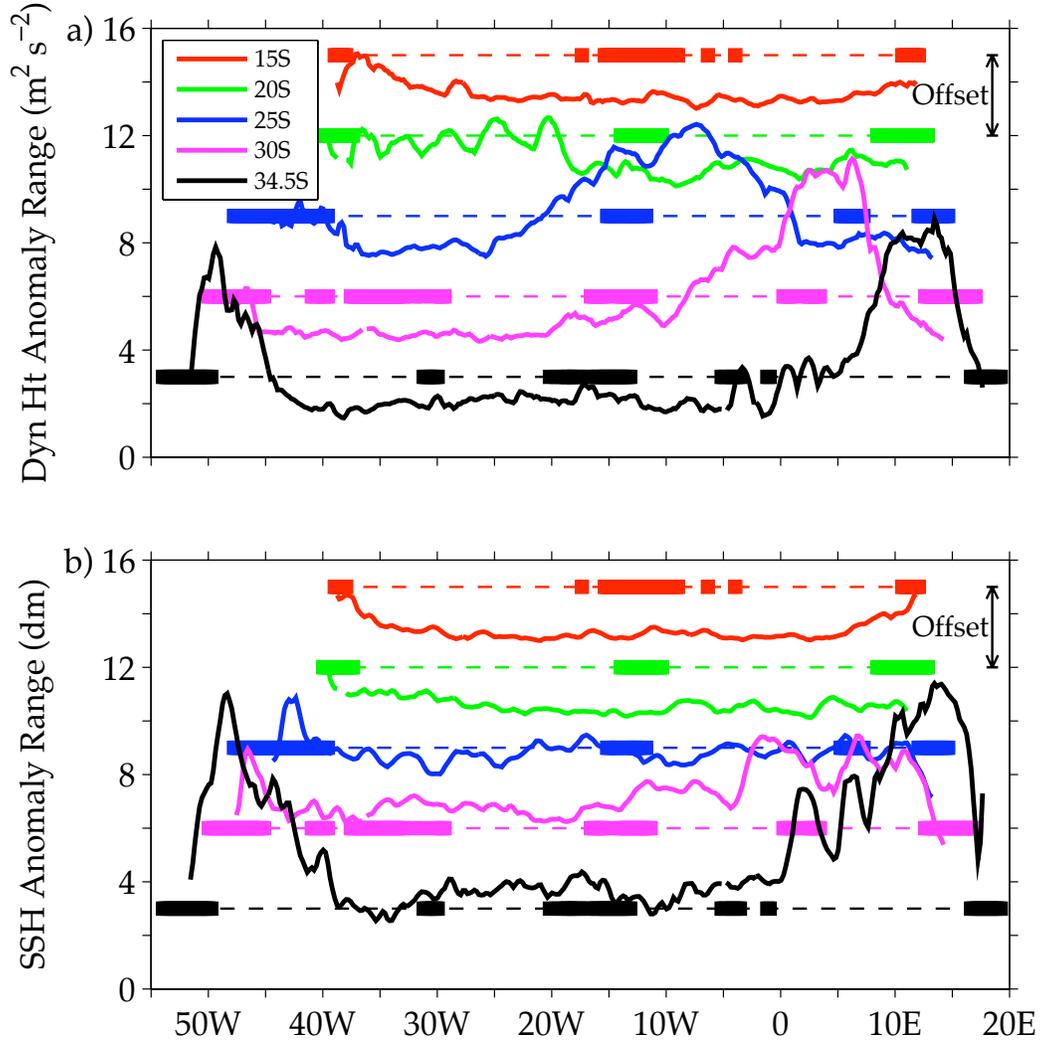

FIG. 9. a) Dynamic range of OFES geopotential height anomalies (in $m^2 s^{-2}$) along 15°S (red), 20°S (green), 25°S (blue), 30°S (magenta), and 34.5°S (black). b) Dynamic range of AVISO SSHA (in dm). Values only shown where bottom depth exceeds 1000 m . An offset is applied from one latitude to the next (dashed lines show reference value of $3 m^2 s^{-2}$ ($3 dm$) for each latitude). The thick horizontal bars indicate regions where bottom depth is shallower than 3500 m .

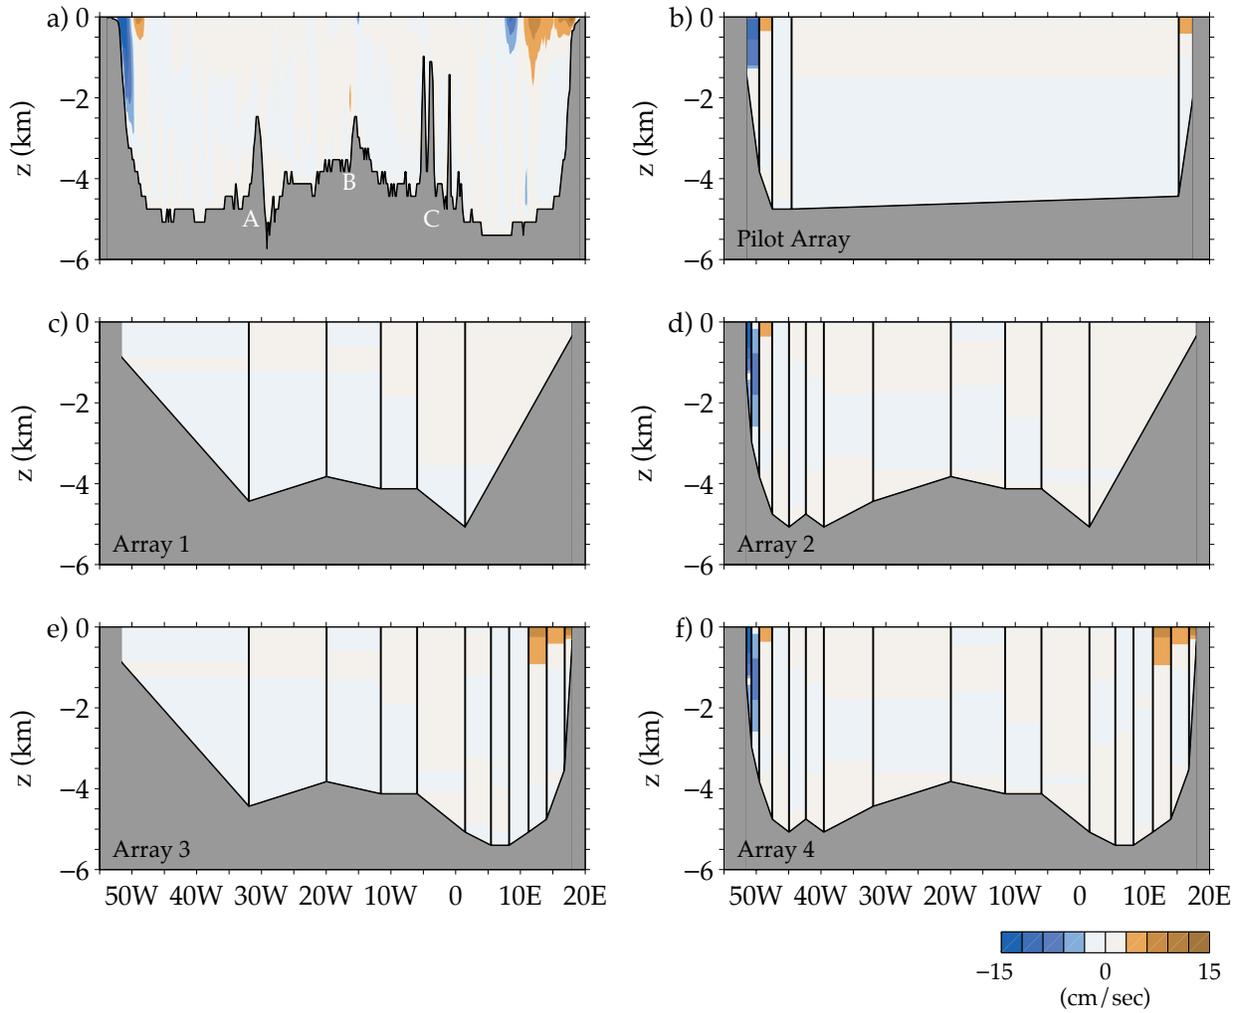

FIG. 10. OFES mean v_g using density profiles for a) full model resolution, b) the pilot array, c) Array 1, d) Array 2, e) Array 3, and f) Array 4. Topographic features such as the Rio Grande Rise and the Mid-Atlantic and Walvis Ridges are identified in panel a) by the labels A, B, and C, respectively.

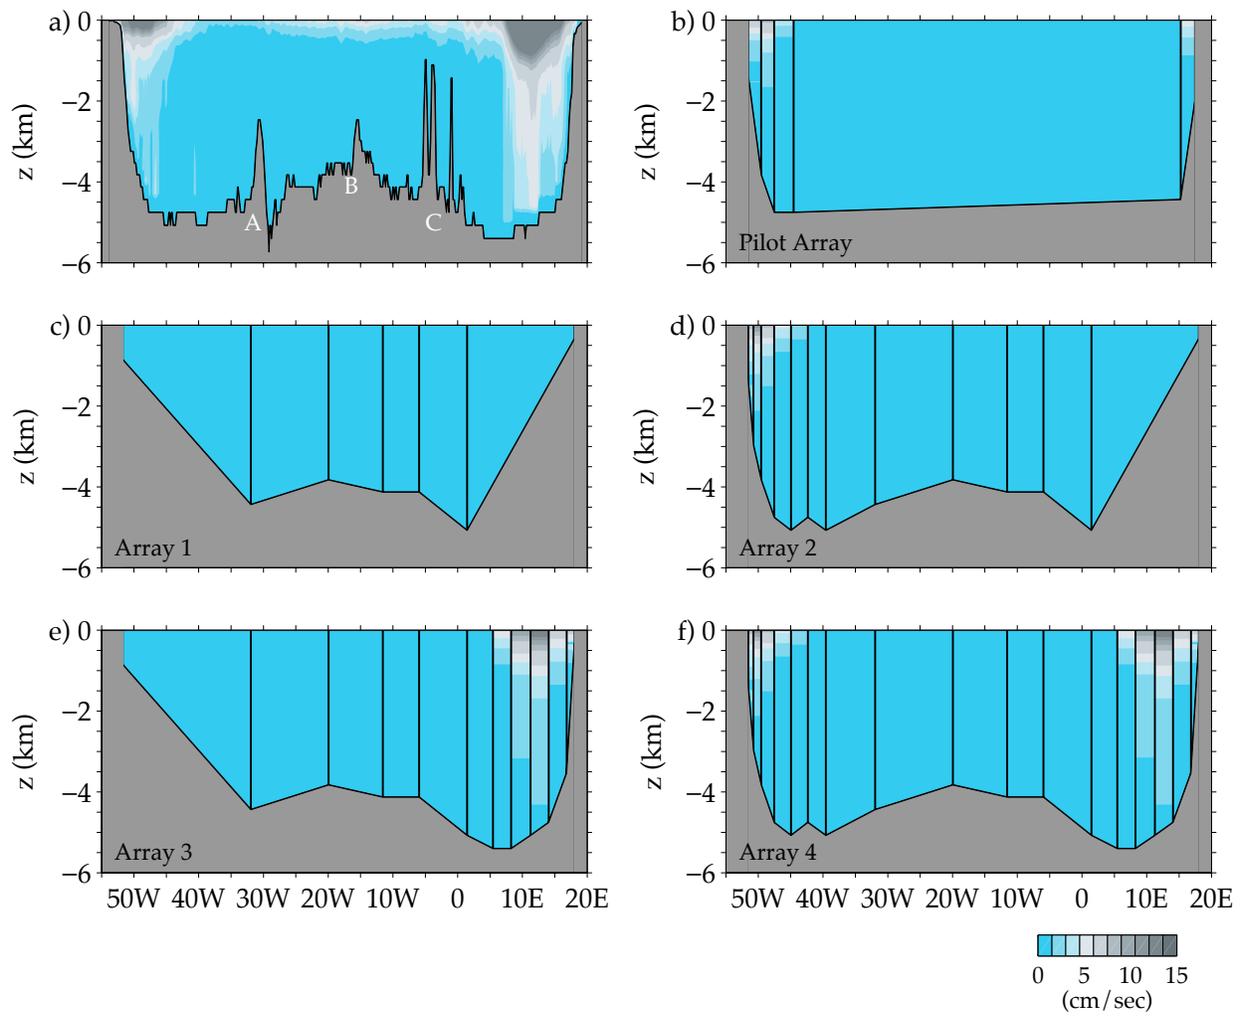

FIG. 11. Same as Figure 10 except for standard deviation of v_g .

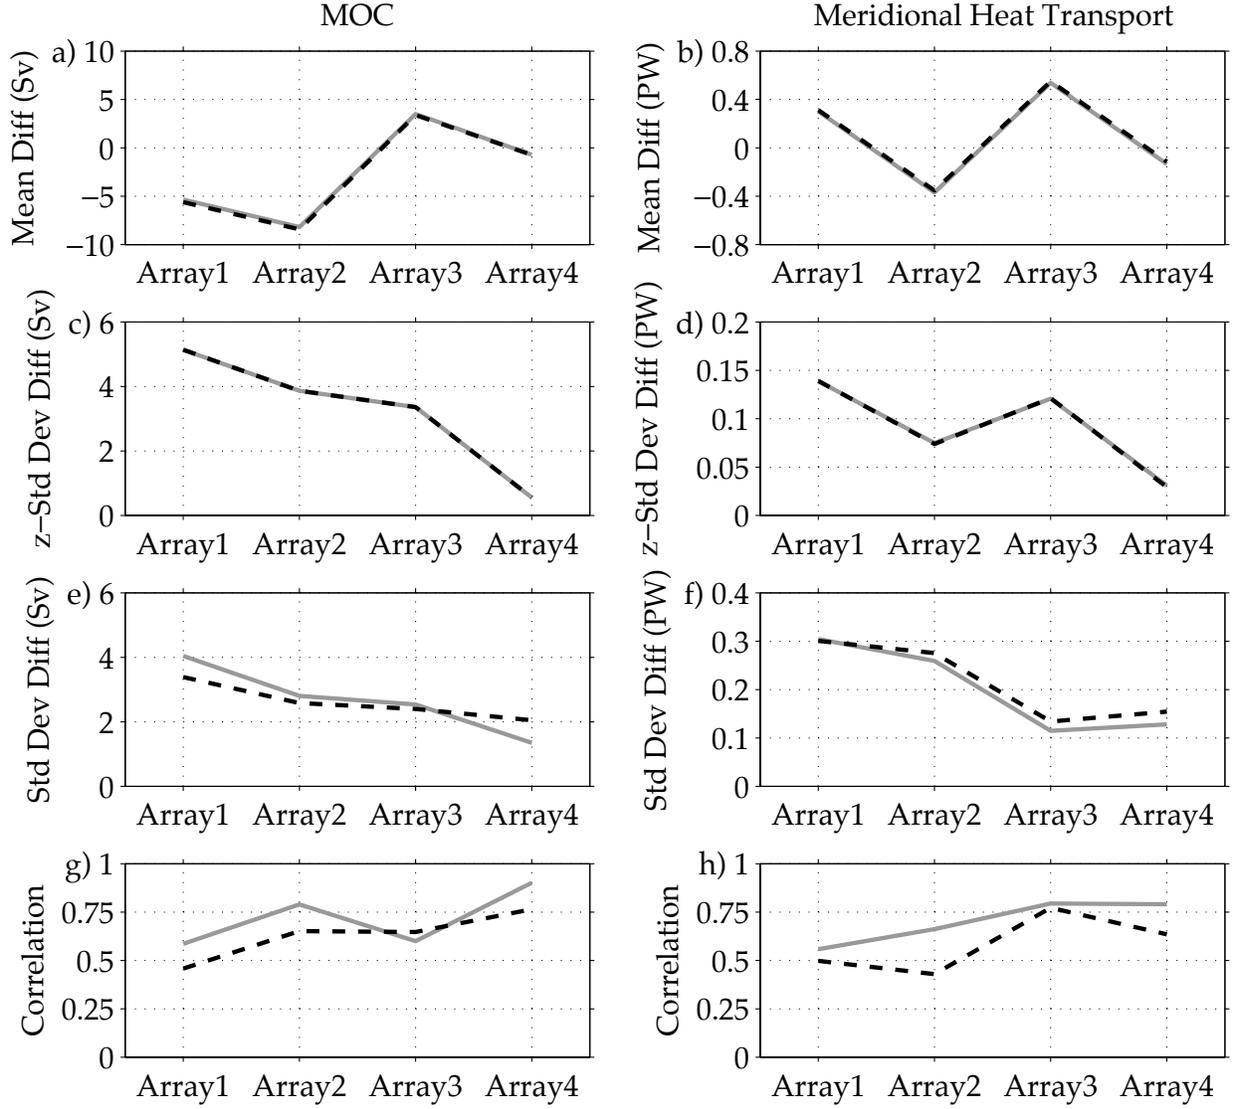

FIG. 12. OFES reconstruction statistics for the reduced T, S (gray solid line) and reduced CPIES (black dashed line) arrays 1 to 4. Left panels correspond to the MOC reconstruction, and right panels correspond to the MHT reconstruction. Shown here are the a-b) mean of $MOC_{array} - MOC$ and $Q_{array} - Q$, c-d) standard deviation of $G_{V,array} - G_V$ and $G_{H,array} - G_H$ (see Fig. 13), e-f) standard deviation of $MOC_{array} - MOC$ and $Q_{array} - Q$, g-h) correlation between MOC_{array} and MOC and Q_{array} and Q . Time scales shorter than 9 months have been removed.

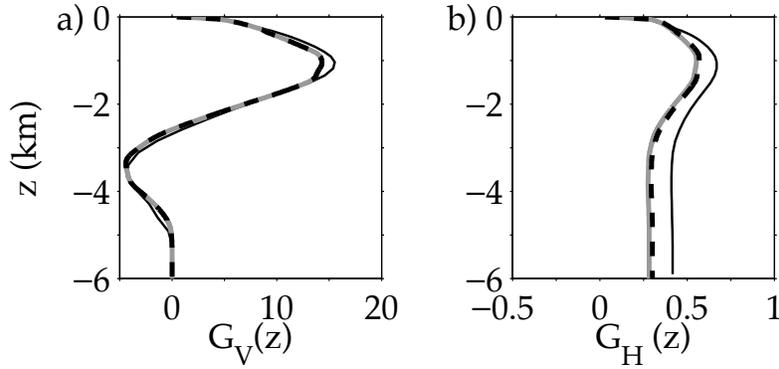

FIG. 13. A comparison of the OFES a) time-mean vertically integrated meridional volume transport $G_V(z)$ (thin black line) with volume transport from T, S Array 4 $G_{V,TS4}$ (gray solid line) and CPIES Array 4 $G_{V,CPIES4}$ (black dashed line) and b) time-mean vertically integrated meridional heat transport $G_H(z)$ (thin black line) with heat transport from T, S Array 4 $G_{H,TS4}$ (gray solid line) and CPIES Array 4 $G_{H,CPIES4}$ (black dashed line). Units are in Sv and PW , respectively.

776 **List of Tables**

777 1 Statistics for OFES (subscript O) and POCM (subscript P) MOC at five
778 latitudes. Mean strength (μ) and standard deviation (σ) of MOC(t), as well
779 as inter-model bias, standard deviation of the difference $MOC_O - MOC_P$,
780 and the correlation between MOC_O and MOC_P . Time scales shorter than 9
781 months have been removed. 53

782 2 Statistics for OFES (subscript O) and POCM (subscript P) MHT at five
783 latitudes. Mean strength (μ) and standard deviation (σ) of MHT, as well as
784 inter-model bias, standard deviation of the difference $Q_O - Q_P$, and correlation
785 between Q_O and Q_P . Time scales shorter than 9 months have been removed. 54

786 3 Correlation (r) and slope (s) of linear regression between MHT and the MOC.
787 Time scales shorter than 9 months have been removed. 55

788 4 Signal-to-noise (SNR) ratio for the MOC (ratio of standard deviation of MOC
789 to the standard deviation of the difference $MOC_{CPIES} - MOC$) and MHT
790 (ratio of standard deviation of Q to the standard deviation of the difference
791 $Q_{CPIES} - Q$) for OFES and POCM simulations. 56

792 5 The locations of the pilot array instruments and those of four reduced arrays
793 deployed in OFES along 34.5°S 57

TABLE 1. Statistics for OFES (subscript O) and POEM (subscript P) MOC at five latitudes. Mean strength (μ) and standard deviation (σ) of MOC(t), as well as inter-model bias, standard deviation of the difference $MOC_O - MOC_P$, and the correlation between MOC_O and MOC_P . Time scales shorter than 9 months have been removed.

TABLE 3. Correlation (r) and slope (s) of linear regression between MHT and the MOC.

Time scales shorter than 9 months have been removed.

Latitude	r_O	r_P	$s_O(PW/Sv)$	$s_P(PW/Sv)$
15°S	0.91	0.87	0.058	0.044
20°S	0.94	0.87	0.057	0.054
25°S	0.91	0.91	0.060	0.058
30°S	0.95	0.92	0.069	0.068
34.5°S	0.96	0.91	0.054	0.055

TABLE 4. Signal-to-noise (SNR) ratio for the MOC (ratio of standard deviation of MOC to the standard deviation of the difference $MOC_{CPIES} - MOC$) and MHT (ratio of standard deviation of Q to the standard deviation of the difference $Q_{CPIES} - Q$) for OFES and POCM simulations.

Latitude	SNR_{MOC}	SNR_{MOC}	SNR_Q	SNR_Q
	OFES	POCM	OFES	POCM
15°S	0.9	1.5	0.5	0.6
20°S	1.3	1.2	0.8	0.8
25°S	1.1	1.7	0.7	0.8
30°S	2.2	1.3	1.2	0.8
34.5°S	2.0	2.3	1.2	1.4

TABLE 5. The locations of the pilot array instruments and those of four reduced arrays deployed in OFES along 34.5°S.

Description	Reduced Array	Longitude of Nearest OFES Gridpoint
Pilot Array		51.55°W, 49.55°W, 47.55°W, 44.55°W, 15.25°E, 17.45°E
West1	1,2,3,4	51.75°W
West2-West8	2,4	51.55°W, 50.75°W, 49.75°W, 47.55°W, 45.15°W, 42.35°W, 39.55°W
Int1-Int5	1,2,3,4	31.95°W, 19.95°W, 11.55°W, 5.95°W, 1.25°E
East6-East2	3,4	5.45°E, 8.25°E, 11.25°E, 14.05°E, 16.85°E
East1	1,2,3,4	18.05°E
